Figure 12  $\delta(^{13}\text{C})$  chemical shift values of the complex  $(\text{COT})\text{Fe}(\text{CO})_3$  compared with those of the free COT.

## Carbon

$^{13}\text{C}$  NMR spectroscopy is an extremely useful technique in organometallic chemistry. The following trends are generally found: saturated carbons appear in the range 0–100 ppm, electronegative substituents on them increasing the shift. Chemical shifts for aromatic carbons are in the range 110–170 ppm, but  $\pi$ -bonded metal alkene may be shifted up to 100 ppm: the shift is strongly dependent on the mode of coordination. Metal carbonyls span from 170 to 290 ppm (they show long relaxation times that make their detection difficult). Metal carbene exhibits resonances in the range 250–370 ppm. A trend of  $\delta(^{13}\text{C})$  chemical shift is reported in Figure 11, whereas in Figure 12 a simulated  $^{13}\text{C}$  NMR spectrum for free cyclohepta- triene has been compared with the data reported for

the coordinated cycloheptatriene in ( $\eta^4$ -cycloheptatriene)Fe(CO)<sub>3</sub>.

## Silicon

<sup>29</sup>Si NMR is a low sensitivity nucleus, which generally yields sharp lines. It has a wide chemical shift range useful for the determination of chemical environment in silicon compounds. It is worth noting that the spectra always contain a background signal from the glass in the tube and probe at 90 ppm. The commonly used reference compound is SiMe<sub>4</sub>. Although several researchers will not find a general need for this technique, as a solution technique it is only slightly more difficult than a <sup>13</sup>C experiment in most cases (solid-state <sup>29</sup>Si NMR is a valuable tool for zeolites and solid-state chemistry). The inductive effect of Si typically moves <sup>1</sup>H NMR aliphatic resonances upfield to ~0–0.5 ppm, making assignment of Si-containing groups rather easy. In addition, both carbon and proton spectra display Si satellites comprising 4.7% of the signal intensity.

Although the important earlier work on <sup>29</sup>Si used indirect <sup>1</sup>H–(Si) double resonance method of detection, the preferred method is now the direct Fourier transform technique by using special pulse sequences as INEPT and DEPT to effect spin polarization transfer from protons and hence achieving dramatic increases in the signal-to-noise ratio with corresponding reductions of spectral accumulation times. Much work has been done on <sup>29</sup>Si NMR in the solid state using magic angle spinning (MASS) and cross-polarization (CP) methods. The overall chemical shift range known is now ~600 ppm for silicon and the pattern is shown in Figure 13. An increase in coordination number from four to five or six produces a significant increase in the shielding of tetravalent silicon. It has been found that in cationic and neutral hexacoordinate silicon complexes such as those reported in Figure 14 the  $\delta(^{29}\text{Si})$  ranges from –198 to –188 ppm, i.e., to lower frequencies with respect to four-coordinate species and show little dependence on the nature of R groups or indeed upon the formal charge on silicon. Five coordinate species as that in Figure 15 exhibit  $\delta(^{29}\text{Si})$  in the range –180 to –160, again at low frequency with respect to four-coordinate species. Silicon can participate in  $p_\pi$ – $p_\pi$  bonding and this fact can lead to significant changes in the chemical shift: for example the silene species containing an  $sp^2$ -hybridized silicon atom exhibit a  $\delta(^{29}\text{Si}) = +41.4$  ppm. The existence of  $d_\pi$ – $d_\pi$  interaction when it is bonded to transition metals does not produce sensible variation on the

Figure 13 Trend of  $\delta(^{29}\text{Si})$  chemical shifts.

Figure 14 Diketonate complexes of Si.

Figure 15 Five-coordinate organosilicon compound.

chemical shifts values. Also polymeric siloxanes can be easily investigated by NMR. The silicon atoms in terminal  $\text{R}_3\text{SiO}-$ , chain  $\text{R}_2\text{Si}(\text{O}-)_2$ , branch  $\text{R}-\text{Si}(\text{O}-)_3$  and quaternary  $\text{Si}(\text{O}-)_4$  groups have very different chemical shifts that makes it possible to study both the polymerization degree and cross-linking. Good correlations have been found between the coupling constants and the s character and/or effective nuclear charge of the central atom: in  $\text{Me}_3\text{SiX}$ , the  $^1J(^{29}\text{Si}, ^{13}\text{C})$  is linearly related to the electronegativity of X. Analogous correlations have been found for  $\text{Me}_n\text{Si}(\text{OEt})_{4-n}$ ,  $(\text{Me}_3\text{Si})_3\text{COR}$ , silyl acetylenes, and tetraorganosilanes.

## Tin, Germanium, and Lead

Group 14 of the periodic table has generally favorable NMR properties: with the exception of Ge, all elements have at least one spin 1/2 isotope of good sensitivity. Moreover, in the past years, one-dimensional (1D) and two-dimensional (2D) proton detected heteronuclear correlation NMR techniques

involving  $^{119}\text{Sn}$  and  $^{207}\text{Pb}$  nuclei have been used for applications in organometallic NMR. Germanium possesses only one magnetic isotope,  $^{73}\text{Ge}$ , with spin  $9/2$ . Tin possesses three magnetically active tin isotopes with spin  $I = 1/2$  ( $^{115}\text{Sn}$ ,  $^{117}\text{Sn}$ ,  $^{119}\text{Sn}$ ). Two of them,  $^{117}\text{Sn}$  and  $^{119}\text{Sn}$  have an appreciable natural abundance and receptivities  $\sim 20$  and  $25$  times greater, respectively, than that of  $^{13}\text{C}$ .  $^{207}\text{Pb}$ , the only lead isotope with spin  $1/2$  (the natural abundance is  $\sim 22\%$ ), has a positive gyromagnetic ratio. Germanium, tin, and lead chemical shifts cover a very large range if inorganic and organometallic compounds are examined: more than  $1200$  ppm for  $^{73}\text{Ge}$ ,  $5000$  ppm for  $^{119}\text{Sn}$ , and  $12\,000$  ppm for  $^{207}\text{Pb}$ . Table 8 exhibits selected  $^{73}\text{Ge}$ ,  $^{119}\text{Sn}$ , and  $^{207}\text{Pb}$  data, all referred to  $(\text{Me})_4\text{E}$  ( $\text{E} = \text{Ge}, \text{Sn}, \text{or Pb}$ ), a negative sign indicating a higher shielding or a shift to lower frequencies. Tin, germanium, and lead chemical shifts are not very sensitive to temperature in the absence of chemical changes (association, dissociation, changes in the coordination number). Shielding of the  $^{119}\text{Sn}$  nucleus generally increases roughly linearly with increasing temperature. Change in the solvent, in the absence of solvent-solute chemical interactions, autoassociation or dissociation affects the tin, germanium, and lead chemical shifts only slightly with respect to their chemical shift ranges. The knowledge of  $\delta(^{119}\text{Sn})$  chemical shifts is very important for predicting the geometry of coordination polyhedra of tin compounds in solution. In the case of tetravalent tin compounds, an increase in tin coordination number from four to five corresponds to an increase in tin

shielding by  $\sim 150$ – $200$  ppm. The magnitude of the chemical shift can permit determination of association constants between the tin compound and the solvent. In several organometal derivatives, changes in the coordination number can arise from self-association, as in the case of organotin alkoxides. Several  $\text{R}_4-n\text{Sn}(\text{OR}')_n$  compounds show values of chemical shifts suggesting self-association as neat liquid or in noncoordinating solvents. For example butyltin(IV) trialkoxides with an unbranched alkoxy group (such as  $\text{BuSn}(\text{OMe})_3$ ) are six-coordinate at room temperature, the association presumably involving octahedral structures with both bridging and not bridging alkoxy oxygen atom. The effect of ligand electronegativity can be demonstrated by the changes of  $^{119}\text{Sn}$  chemical shifts along the series  $\text{R}_n\text{SnCl}_{4-n}$  ( $\text{R} = \text{alkyl or aryl}$ ) as the values of  $n$  changes from 2 to 0. However, the plot (Figure 16) of the  $\delta(^{119}\text{Sn})$  for the compounds  $\text{R}_n\text{SnCl}_{4-n}$  indicates clearly that

**Figure 16** Plot of  $\delta(^{119}\text{Sn})$  against  $n$  for a series of monomeric organotin(IV) compounds:  $\Delta$ , Me;  $\blacksquare$ , Bu; and  $\bullet$ , Ph.

**Table 8** Selected  $^{73}\text{Ge}$ ,  $^{119}\text{Sn}$ , and  $^{207}\text{Pb}$  NMR chemical shifts in parts per million relative to  $\text{Me}_4\text{E}$  ( $\text{E} = \text{Ge}, \text{Sn}, \text{and Pb}$ )

Me, methyl; Et, ethyl; Vi, vinyl; Ph, phenyl.

there are no obvious general relationships between  $\delta(^{119}\text{Sn})$  and the ligand electronegativity. The U-shaped trend is usually assigned to change in the paramagnetic term due to p electron imbalance, generally maximum at  $n=2$ . In a series of methylvinylgermanes, the  $^{73}\text{Ge}$  chemical shifts were compared with those of the corresponding methylvinylsilanes, and the correlation  $\delta(^{73}\text{Ge}) = 1.96 \delta(^{29}\text{Si}) + 2.37$  was found. It has been found that the magnitude of the chemical shift cannot be simply assigned to the electron densities, but relative contributions of the diamagnetic and paramagnetic terms to the  $^{73}\text{Ge}$  chemical shift should be considered.

MO calculations indicate in monomeric tin(II) compounds such as stannocene,  $(\text{C}_5\text{H}_5)_2\text{Sn}$ , a highly shielded tin atom ( $-2199$  ppm in  $\text{C}_6\text{H}_{12}$ ) as a consequence of an inefficient paramagnetic charge circulation due to the high LUMO energy of this molecule. The values of the chemical shift ( $\delta(^{119}\text{Sn})$ ) of diphenyl-, dibenzyl-, and di-n-butyl-tin(IV) compounds exhibit a good mutual correlation which can be expressed by eqn [3]:

$$\delta(^{119}\text{Sn})[\text{R}'_2\text{Sn}] = a \times \delta(^{119}\text{Sn})[\text{R}''_2\text{Sn}] + b \quad [3]$$

where  $[\text{R}'_2\text{Sn}]$  and  $[\text{R}''_2\text{Sn}]$  represent pairs of diorganotin(IV) compounds with different substituents, and  $a$  and  $b$  represent the slope and the intercept of the linear correlations.

The valence electron-mediated nuclear spin-spin couplings,  $J(^{73}\text{Ge}, \text{X})$ ,  $J(^{117}\text{Sn}, \text{X})$ ,  $J(^{119}\text{Sn}, \text{X})$ , and  $J(^{207}\text{Pb}, \text{X})$ , are dominated by the 'FERMI contact' term arising from the interaction of the nuclear spin magnetic dipole with the electron spin, which has a finite density at the nucleus. In the case of  $\text{X} = ^1\text{H}$ ,  $^{19}\text{F}$ ,  $^{31}\text{P}$ , highly abundant spin 1/2 nuclei, the  $^nJ(\text{E}, \text{X})$  data are obtained conveniently from the X atom NMR spectra, whereas in the case of couplings with rare spin 1/2 nuclei ( $\text{X} = ^{13}\text{C}$ ,  $^{29}\text{Si}$ ,  $^{15}\text{N}$ ), the  $^nJ(\text{E}, \text{X})$  can be obtained also from E NMR spectra, by using Hahn-echo extended pulse sequences. Table 9 gives a selection of the values of the coupling constants in germanium, tin, and lead compounds. Spin couplings involving  $^{73}\text{Ge}$  have been generally reported only in highly symmetrical compounds. In Figure 17 the  $^1\text{H}$  NMR spectrum of  $\text{GeH}_4$  is reported. The 10 evenly spaced lines are due to 8% of the molecules, which contain  $^{73}\text{Ge}$  ( $I=9/2$ ), whereas the intense central line arises from all other isotopic species. A simple linear relationship between  $J(^{119}\text{Sn}, ^{13}\text{C})$  coupling constants of a group of dimethyltin(IV) compounds and their C-Sn-C angles ( $\theta$ ) has been found on the basis of the analysis of a large set of experimental data (eqn [4])

$$|J(^{119}\text{Sn}, ^{13}\text{C})| = (10.7 \pm 0.5)\theta - (778 \pm 64) \quad [4]$$

**Table 9** Some representative spin couplings, involving  $^{73}\text{Ge}$ ,  $^{119}\text{Sn}$ , and  $^{207}\text{Pb}$

Compound	X	E	$^1J(\text{E}, \text{X})$ values (Hz)

<sup>a</sup>  $^2J(^{73}\text{Ge}, ^1\text{H}) = +3.0$  Hz.

**Figure 17**  $^1\text{H}$  NMR spectrum of  $\text{GeH}_4$ .

The replacement of alkyl groups on  $\text{R}_4\text{M}$  with electro-negative substituents causes an increase in the magnitude of  $^1J(\text{M}, ^{13}\text{C})$  as the result of the greater  $\sigma$  character in the Sn-C orbital.

## Phosphorus

The  $^{31}\text{P}$  NMR technique is very useful due to the fact that it is easier than  $^{13}\text{C}$ . Although the chemical shift range is not as diagnostic as with other nuclei, the

**Figure 18** Trend of  $\delta(^{31}\text{P})$  chemical shifts.

magnitude of  $^1J(^{31}\text{P}, \text{X})$  coupling constants is useful for the assignment of structures.

$^{31}\text{P}$  is spin 1/2, 100% abundant, and has a receptivity relative to the  $^1\text{H}$  of 0.0063. The range of chemical shifts is *c.*  $\pm 250$  ppm from  $\text{H}_3\text{PO}_4$ , however, very different values corresponding to highly shielded or deshielded molecule have been reported in literature, as the two extremes  $\text{P}_4$  ( $-460$  ppm) and the phosphinidene complex  $[\text{tBuP}[\text{Cr}(\text{CO})_5]_2$  ( $+1362$  ppm). Interpretation of the shift is not easy, there seems to be many contributing factors. The  $\delta(^{31}\text{P})$  at a first approximation is determined by the number and type of directly bound atoms and is relatively little affected by consideration of charge and structure. A pattern of chemical shifts for the three-coordinate P compounds is depicted in **Figure 18**. P(III) covers the whole normal range and depends strongly on the substituents. Coordination of a P(III) compound to a metal results in a coordination shift from the original resonance position of the uncoordinated ligand. In **Table 10** selected values of coordination shifts for some representative compounds are reported. With a restricted number of ligands an approximate linear correlation was found between the coordination shift,  $\Delta\delta$  and the chemical shift. The coordination shifts were mostly in the direction of decreased shielding relative to the free ligand and the shifts were larger (more positive) with highly shielded ligands. Unknown values can be predicted by extrapolation or interpolation as indicated in

**Table 10**  $\delta(^{31}\text{P})$  ligand chemical shifts (ppm) and coordination shifts (ppm)<sup>a</sup> in Cr, Mo, and W complexes containing P-donor molecules

Ligand	Ligand shift	$\text{Cr}(\text{CO})_5 \text{L}$ ( $\delta$ )	$\text{Mo}(\text{CO})_5 \text{L}$ ( $\Delta\delta$ )	$\text{W}(\text{CO})_5 \text{L}$ ( $\Delta\delta$ )
$\text{PH}_3$	-239	109	74	51
$\text{PMe}_3$	-62	69	45	26
$\text{PMePh}_2$	-28	63	43	24
$\text{P}^i\text{Bu}_3$	-33	63	45	26

$\text{P}(\text{NMe}_2)_3$	123		23	
$\text{P}(\text{OEt})_3$	138		18	
$\text{P}(\text{OPh})_3$	128		26	
$\text{P}(\text{OMe})_3$	141	39	21	-4

<sup>a</sup>Coordination shift ( $\Delta\delta$ ) =  $\delta(\text{complex}) - \delta(\text{ligand})$ .

**Figure 19** Interpolation can help in the prediction of  $\delta(^{31}\text{P})$  values.

**Figure 19.** P(V) compounds exhibit a narrower range  $\delta(^{31}\text{P})$  spanning from  $-50$  to  $+100$  ppm.

Coupling constants involving  $^{31}\text{P}$  have been measured for most of the magnetically active nuclei. Their magnitudes can be very large, reaching 12 kHz in some Hg complexes. The couplings are very sensitive to the phosphorus substituents, hybridization, and oxidation state, and generally increase in magnitude with substituents' electronegativity and show an algebraic increase in reducing coupling constant from P(III) to P(V).

The measurements of  $^2J(^{31}\text{P}-\text{M}-^{31}\text{P})$  where the intervening atom is a metal has been widely investigated due to a special interest for its value in making stereochemical assignments. The large variations in values may be usefully discussed under these headings: (1) the complex geometry; (2) the nature of the metal; and (3) the nature of the substituents on phosphorus. It has been found that coupling between phosphorus atoms in mutually *trans* relationship are large and positive, whereas *cis* phosphorus lead to small and often negative values. There is a general tendency for  $^2J(^{31}\text{P}-\text{M}-^{31}\text{P})$  to become more positive

as one descends a transition metal triad, and finally the  $^2J(^{31}\text{P}-\text{M}-^{31}\text{P})$  generally increases in magnitude with increasing electronegativity of substituents on P.

The Karplus angle relationship works quite well for organometallic phosphine complexes. For example in the compound  $[\text{Ir}(\text{PMe}_3)_3\text{HCl}(\text{C}_5\text{H}_5\text{N})]$ , the  $^2J(^{31}\text{P}, ^1\text{H})$  is 153.5 Hz for the  $\text{PMe}_3$  *trans* to the hydride, but only 19.8 Hz to the (chemically equivalent) *cis* phosphines.

## Arsenic, Antimony, and Bismuth

All the elements of group 15 of the periodic table possess at least one isotope suitable for investigation by NMR spectroscopy. The magnetically active isotopes of arsenic, antimony, and bismuth ( $^{75}\text{As}$ ,  $I = 3/2$ ;  $^{121}\text{Sb}$ ,  $I = 5/2$ ;  $^{123}\text{Sb}$ ,  $I = 7/2$ ;  $^{209}\text{Bi}$ ,  $I = 9/2$ ) have high abundance and relatively high sensitivity; however, they have been scarcely employed in multinuclear NMR spectroscopy owing to their high spin quantum numbers, which produce large quadrupolar moments. The Group 15 nuclides can be studied by NMR spectroscopy only when the compounds containing these elements are highly symmetric in the oxidation state +5. These nuclides are spectroscopically silent in nonsymmetric compounds or in the +3 oxidation state. The chemical shift standards (generally used at room temperature) are  $0.1 \text{ mol l}^{-1}$   $[(\text{Et}_4\text{N})^+(\text{AsF}_6)^-]$  in  $\text{CH}_3\text{CN}$  for  $^{75}\text{As}$ ,  $0.3 \text{ mol l}^{-1}$   $[(\text{Et}_4\text{N})^+(\text{SbCl}_6)^-]$  in  $\text{CH}_3\text{CN}$  for  $^{121,123}\text{Sb}$ , and a saturated solution of  $[(\text{Me}_4\text{N})^+(\text{BiF}_6)^-]$  in  $\text{CH}_3\text{CN}$  for  $^{209}\text{Bi}$ .  $^{75}\text{As}$ ,  $^{121,123}\text{Sb}$ , and  $^{209}\text{Bi}$  chemical shift ranges are very large (selected values are reported in Table 11). A positive sign indicates a chemical shift

to higher frequency (lower shielding) with respect to the reference compound. In the case of arsenic (+5) derivatives, the chemical shift range spans  $\sim 700$  ppm, with the tetrahedral oxoanion  $(\text{AsO}_4)^{3-}$  and the cation  $(\text{AsH}_4)^+$  occupying the deshielded and the shielded ends of the range, respectively. Even if there seems to be no regularity among the shifts of the  $\text{AsR}_4^+$  compounds, the ordering in terms of alkyl substituent is consistent with that found for group 14 alkyls, labeling the atoms of the structural unit  $[\text{As}(\text{alkyl})_4]^+$  as  $\text{As}_\alpha-\text{C}_\beta-\text{C}_\gamma-\text{C}_\delta$ , methyl substitution for one hydrogen at the  $\beta$  position ( $\Delta\beta$ ) deshields by 11 ppm,  $\Delta\gamma$  shields by 5 ppm, and  $\Delta\delta$  shields by 1 ppm. This trend in shielding effect as one proceeds down the chain is characteristic of methyl substitution. The antimony chemical shift range spans  $\sim 3500$  ppm. To date  $(\text{SbS}_4)^{3-}$  and  $\text{SbBr}_6^-$  occupy the deshielded ends of the range. In  $(\text{SbF}_6)^-$  and  $(\text{SbCl}_6)^-$  the small difference between the antimony shifts ( $\sim 87$  ppm) compared with those for analogous  $^{31}\text{P}$  and  $^{75}\text{As}$  species (152 and 392 ppm, respectively) is probably due to the electronic excitation energy that in both antimony, and, more likely, arsenic is responsible for the anomalous shielding term. In the case of the heaviest bismuth nuclide, only a few  $^{209}\text{Bi}$  NMR data are available yet.

In the case of  $^{75}\text{As}$ , only one  $J(^{75}\text{As}-^1\text{H})$  (555 Hz) value related to the  $(\text{AsH}_4)^+$  cation, has been reported. The  $\Delta\nu_{1/2}$  values for arsenic compounds, unlike  $^{75}\text{As}$  chemical shifts, are generally strongly dependent on the type of solvent employed, partly surely owing to ion pairing; in fact, the linewidths for  $(\text{AsEt}_4)^+\text{Br}^-$  are reported to be 168, 455, 670, and 700 Hz in water, acetonitrile, dimethylformamide, and dimethylsulfoxide, respectively.

## Selenium and Tellurium

$^{77}\text{Se}$  and  $^{125}\text{Te}$  are of moderate and good NMR receptivity, respectively. Coupling constants to nuclei such as the  $^1\text{H}$ ,  $^{13}\text{C}$ , and  $^{31}\text{P}$  are normally obtained from the positions of the satellites in the spectra of these nuclei. In Table 12 selected  $^{77}\text{Se}$  and  $^{125}\text{Te}$  chemical shifts relative to  $\text{Me}_2\text{Se}$  and  $\text{Me}_2\text{Te}$ , respectively, are reported. It has been generally found that variations up to  $\sim 10$  ppm with solvent and temperature can occur for  $^{77}\text{Se}$ . A study carried out on  $\text{Me}_2\text{Se}$  and  $\text{Me}_2\text{Te}$  in 30 different solvents indicates a degree of correlation between  $V_{\text{max}}$  and the solvent. The shifts in the series  $\text{SeR}_2$  increase in the order  $\text{R} = \text{Me} < \text{Et} < ^i\text{Pr} < ^t\text{Bu}$ .

Selenium and tellurium shielding generally runs closely parallel in equivalent compounds, plot of  $\delta(^{125}\text{Te})$  against  $\delta(^{77}\text{Se})$  being linear with a slope of  $\sim 1.8$ . An investigation on closely correlated

**Figure 20** Correlation between chemical shifts of analogous selenium and tellurium compounds.

compounds  $\text{R}^1\text{R}^2\text{E}$  ( $\text{E} = \text{Se}$  or  $\text{Te}$ ,  $\text{R}^1, \text{R}^2 = \text{unsaturated groups}$ ) reported  $\delta(^{125}\text{Te}) = 1.61 \delta(^{77}\text{Se})$  (Figure 20). It has been established that electron withdrawal from selenium or tellurium will lead to decreased shielding, as emerges from the chemical shifts of  $\text{MeSe}^-$ ,  $\text{Me}_2\text{Se}$ , and  $\text{Me}_3\text{Se}^+$  and from the low frequency shift of  $\text{R}_3\text{PE}$  ( $\text{E} = \text{Se}$  or  $\text{Te}$ ). It has been found that in the series  $\text{CF}_3\text{SeX}$   $\delta(^{77}\text{Se})$  correlates well with the electronegativity of  $\text{X}$  ( $\text{Cl}$ ,  $\text{Br}$ ,  $\text{CN}$ ,  $\text{H}$ ,  $\text{Ag}$ ). In a number of aromatic derivatives there are usually correlations between  $\delta(^{77}\text{Se})$  and  $\delta(^{125}\text{Te})$  with Hammett  $\sigma$  and Swain and Lupton substituent parameters. Also the role of stereochemistry in determining  $\text{Se}$  and  $\text{Te}$  chemical shifts has been

investigated. It has been reported that the  $\delta(^{77}\text{Se})$  differs by 2.1 ppm in the two diastereomers of the ester of 2-octanol and 2-phenylselenopropionic acid. On the other hand the difference for the meso and DL forms of  $[\text{PhMeP}(\text{Se})]_2\text{CH}_2$  is  $\sim 17.0$  ppm. In selenoethers, complex selenides, 2-substituted tellurophenes the usual dependence of  $^1J(^{77}\text{Se}, ^{13}\text{C})$  and  $^1J(^{125}\text{Te}, ^{13}\text{C})$  upon the hybridization and/or effective nuclear charge of the participating nuclei has been found.

## Manganese and Tungsten

The relatively high receptivity of  $^{55}\text{Mn}$  and its medium size quadrupole moment (that produces broad lines) make this nucleus a favorable one for NMR detection.  $^{55}\text{Mn}$  exhibits a shift range of  $\sim 3000$  ppm, with lines  $\sim 10$  Hz large in the case of symmetrical environment such as  $\text{MnO}_4^-$  and  $10000$  Hz in the case of unsymmetrical carbonyl-manganese complexes. There is a relationship between the oxidation state and chemical shielding as is noted for other metals. The reference compound is an  $\text{Mn}(\text{VII})$  species:  $\text{MnO}_4^-$ . The range of chemical shift for  $\text{Mn}^{\text{I}}$  species spans from  $-1000$  to  $-1500$ , whereas for  $\text{Mn}^{-\text{I}}$  complexes the range goes from  $-1500$  to  $-3000$  ppm. Only a limited number of diamagnetic organometallic Mn complexes that include isonitriles and carbonyl species have been investigated. The carbonyl-manganese complexes cover the whole  $^{55}\text{Mn}$  shift range with the hydride species generally at the low frequency margin (Table 13).

The first shift value for solid  $[\text{Mn}(\text{CO})_6]^+$  was  $-1500$  ppm. While in the vanadium, niobium, and

<sup>b</sup>Linewidths and chemical shifts are given for solution of the respective complexes.

molybdenum hexacarbonyls replacement of CO results in a decrease of metal shielding, the  $[\text{Mn}(\text{CO})_6]^+$  derivatives may exhibit both substantial increase and decrease of  $^{55}\text{Mn}$  shielding. The complexes  $[\text{Mn}(\text{CO})_{4-n}(\text{PR}_3)_n(\text{S,P-donor})]$  ( $\text{R} = \text{OMe}$ ,  $\text{Ph}$ ,  $\text{Me}$ ,  $\text{Et}$ ,  $\text{Ph}$ ,  $n = 1$  or  $2$ ) exhibit deshielding of the  $^{55}\text{Mn}$  nucleus with an increasing number of phosphines coordinated to Mn. Phosphines are efficient  $\pi$  acceptors and then influence the paramagnetic deshielding term via the  $\pi$ -interacting  $e$  level ( $d_{xz}$ ,  $d_{yz}$ ) of the Mn-3d set under  $C_{4v}$  symmetry. If the ligand–Mn interaction does not allow for much  $\pi$  contribution,  $\sigma$  influences upon the HOMO–LUMO separation may become predominant for variations of  $\delta$  as in  $[\text{MnH}(\text{CO})_{5-n}(\text{PF}_3)_n]$ ,  $[\text{MnX}(\text{CO})_5]$ , and  $[\text{MnSnR}_3(\text{CO})_5]$ .

The diamagnetic and paramagnetic terms for  $[\text{MnX}(\text{CO})_5]$  ( $\text{X} = \text{halide}$ ,  $\text{H}$ ,  $\text{CN}$ ,  $\text{Me}$ ),  $[\text{Mn}(\text{CO})_6]^+$ , and  $[\text{MnO}_4]^-$  have been measured: a qualitative agreement is found between the calculated paramagnetic  $\sigma(\text{para})$  term and the observed shielding. It seems that the main contribution to  $\sigma(\text{para})$  arises from the  $d$ – $d$  excitation. Overall shielding increases with increasing  $\pi$ -donating ability, and via  $\delta_\sigma$ , with increasing hardness, the two partly counteracting effects giving rise to an ordering  $\text{H} < \text{CN} < \text{Me} < \text{Cl} < \text{Br} < \text{I}$ .

The only tungsten isotope with a nonzero value of  $I$  is  $^{183}\text{W}$ ,  $I = 1/2$  (natural abundance 14.4%), a nuclide with low receptivity relative to  $^1\text{H}$  ( $1.06 \times 10^{-5}$ ). This nucleus is radioactive, an  $\alpha$ -particle emitter with a long half-life ( $> 1 \times 10^{17}$  years). Satellite peaks from coupling with  $^{183}\text{W}$  are easily found in the  $^{31}\text{P}$  NMR spectra of tertiary phosphine complexes, in the  $^1\text{H}$  NMR spectra of hydrides, in the  $^{19}\text{F}$  NMR spectra of fluoro complexes, and finally in the  $^{13}\text{C}$  NMR spectra of exclusively carbonyl complexes. A solution of  $\text{Na}_2[\text{WO}_4]$  ( $1 \text{ mol l}^{-1}$  in  $\text{D}_2\text{O}$ , pD 9)

**Table 14**  $^{183}\text{W}$  chemical shifts for selected organotungsten compounds

Compound	$\delta_W$ (ppm)
$\text{W}(\text{CO})_6$	– 3505
$\text{W}(\text{CO})_5(\text{PMePh}_2)$	– 3324
$[\{\text{W}(\text{CO})_3(\text{Cp})\}_2]$	– 4040
$[\text{W}(\text{CO})_3(\text{Cp})\text{Cl}]$	– 2406
$[\text{W}(\text{CO})_3(\text{Cp})\text{Br}]$	– 2584
$[\text{W}(\text{CO})_3(\text{Cp})\text{I}]$	– 2996
$[\text{W}(\text{CO})_3(\text{Cp})\text{Me}]$	– 3549
$[\text{W}(\text{CO})_3(\text{Cp})\text{H}]$	– 4017
$[\text{W}(\text{Cp})_2\text{H}_2]$	– 4671

has been now accepted as the standard reference for  $^{183}\text{W}$  NMR. Relaxation times for  $^{183}\text{W}$  are generally long. Since a major relaxation mechanism is through chemical shift anisotropy (CSA), shorter, more favorable relaxation times are obtained when the environment about the tungsten nucleus is less symmetric. Addition of a paramagnetic substance, such as  $[\text{Cr}(\text{acac})_3]$  can be used to shorten relaxation times which are inconveniently long. The tungsten chemical shift is very sensitive to the environment about the nucleus. The overall range is large ( $\sim 6000$  ppm). Chemical shifts for selected organometallic compounds are reported in Table 14. Variations in chemical shifts for heavy atom are dominated by changes in  $\sigma_p$ , the paramagnetic contribution to total nuclear screening transition metal complex, for which a simplified expression is the following eqn [5]

$$\sigma_p \propto - (r^{-3}) \sum_j \sum_k (E_k - E_j)^{-1} C \quad [5]$$

where  $r$  is the average distance of valence d-electrons from the nucleus,  $E_k$  and  $E_j$  the energies of unoccupied ( $k$ ) and occupied molecular orbitals ( $j$ ), and  $C$  the sum containing the coefficients of the metals s, p, and d orbitals used in the summation to develop the various molecular orbitals.

Three classes of low-valent carbonyl tungsten compounds have been widely investigated:  $[\text{W}(\text{CO})_{6-n}\text{L}_n]$  (where L usually is a  $\text{PR}_3$ ),  $[\text{WCp}(\text{CO})_3\text{R}]$  ( $\text{R} = \text{halide}$ ,  $\text{H}$ ,  $\text{D}$ ,  $\text{alkyl}$ ,  $\text{SnMe}_3$ ),  $[\text{WCp}(\text{CO})_3]$ , and  $[\text{WCp}(\text{PR}_3)(\text{CO})_3]$ . Shielding decreases as CO is successively replaced by a weaker  $\pi$ -acceptor ligand. The  $^{183}\text{W}$  nucleus is more shielded in *trans*- than in *cis*- $[\text{W}(\text{CO})_4\text{L}_2]$  analogously to that found in  $[\text{Mn}(\text{CO})_4\text{L}_2]$  and  $[\text{Mo}(\text{CO})_4\text{L}_2]$ , but opposite trend to that in  $[\text{V}(\text{CO})_4\text{L}_2]^-$ . It will be noted that the tungsten nucleus in the series  $[\text{W}(\text{CO})_3(\text{Cp})\text{X}]$  becomes progressively more shielded as the halide is changed from chloride to bromide to iodide, which is the ‘normal halide dependence’ order for transition metal complexes. This is opposite to the

order expected from the effect of  $X^-$  on excitation energies.

## Cobalt, Rhodium, and Platinum

There is a scarcity of data and results to consider for palladium, osmium, iridium, iron, nickel, and ruthenium, the overall NMR behavior of these six metals being closely similar, although there are variations strictly connected to their chemical features. All group VIII transition metals exhibit a large range of the values of chemical shifts, over 18 000 ppm for  $^{59}\text{Co}$ . The following trends have been found: (1) species with the same donor atoms or with the same groups bonded to the metal are grouped together; (2) complexes of strong field donors resonate at low frequency; (3) donor atoms from lower rows of the periodic table cause lower frequency shifts; and (4) lower oxidation states give lower frequency shifts, but there is considerable overlap between the ranges covered by different oxidation states. The common reference compound for  $^{59}\text{Co}$  NMR is  $\text{K}_3[\text{Co}(\text{CN})_6]$  in  $\text{D}_2\text{O}$ . A large temperature dependence of  $^{59}\text{Co}$  chemical shift was found from the early observations. This behavior, associated with variation of  $\Delta E$ , has been firstly ascribed to the changes in the mean vibrational energies of the ground and excited states and then alternatively, owing to the anharmonicity of vibrations, to an increase of the mean M–L distance and so  $\Delta E^{-1}$  with increasing temperature. The resonance of  $^{59}\text{Co}$  has been proposed as NMR thermometers.

The  $^{59}\text{Co}$  chemical shifts of Co(III) complexes are clearly grouped together according to the identity of the donor atom. In Table 15 selected  $\delta(^{59}\text{Co})$  have been reported. In view of the large line-widths found, often large variations in shift values have been found. Small anisotropy has been found in the low-valent compounds  $[\text{Co}_2(\text{CO})_8]$  and  $[\text{Co}(\text{CO})_4\text{X}]$  where X is  $\text{Mn}(\text{CO})_5$  as also in  $[\text{Co}(\text{NH}_3)_5(\text{CN})]\text{Cl}_2$ ,  $[\text{Co}(\text{NH}_3)_4(\text{CO}_3)]\text{Br}$ , whereas

large anisotropy is in  $[\text{Co}(\text{Cp})_2]\text{NO}_3 \cdot \text{H}_2\text{O}$ . The resonances of  $[\text{Co}(\text{CN})_6]^{3-}$ , and  $[\text{Co}(\text{NO}_2)_6]^{3-}$  moves 22.3 and 46.4 ppm, respectively, to low frequency when a pressure of  $1000 \text{ kg cm}^{-2}$  was applied. The effect of the pressure seems to reduce the metal–ligand distance and then the value of  $\Delta E^{-1}$ .

$^{103}\text{Rh}$  and  $^{195}\text{Pt}$  chemical shifts (Table 16) are used in the investigation of the coordination mode adopted by ambidentate ligands. Replacement of the methyl group in  $[\text{PtCl}_2(\text{Me})\text{CO}]^-$  by larger alkyls causes little changes in  $\delta(^{195}\text{Pt})$ . Table 17 gives typical ranges for some coupling constants to group VIII nuclei. If the bonding terms in the usual equation for one-bond coupling constants are the same, then the coupling constants to two different metals should be in the ratio of their values of  $|\gamma|\psi_s(0)|^2$ .  $^1J(^{195}\text{Pt}, \text{X})$  is 16–22 times  $^1J(^{103}\text{Rh}, \text{X})$ . Relationships between structural features and  $^1J(^{195}\text{Pt}, ^1\text{H})$  and  $^1J(^{195}\text{Pt}, ^{13}\text{C})$

**Figure 21**  $^1\text{H}$  NMR spectrum of *trans*-[Pt(ethylene)(2-carboxypyridine) $\text{Cl}_2$ ] complex showing CSA broadening.

in CO,  $\text{CH}_3$ , and COD (cyclooctadiene) derivatives have been reported. It has been shown that  $^1J(^{195}\text{Pt}, ^{13}\text{C})$  in one isomer of  $[\text{PtCl}(\text{Ph})\text{CO}(\text{PR}_3)]$  increases with the temperature.

CSA relaxation on  $^{195}\text{Pt}$  can have unexpected influence on proton satellites. CSA relaxation increases with the square of the applied field. Olefinic  $^1\text{H}$  NMR signal of *trans*-Pt(ethylene)(2-carboxypyridine) $\text{Cl}_2$  at 80 and 400 MHz showed severe CSA broadening of the  $^{195}\text{Pt}$  satellites at the higher field (Figure 21).

Coupling to the  $I = 1/2$  Rh nucleus is often a powerful tool, particularly in Rh-phosphines and Rh-carbonyl complexes. In the  $^{13}\text{C}$  NMR spectrum of  $[\text{Rh}_2(\text{CO})_3(\text{CH}_2(\text{Cp}))]$ , the bridging carbonyl is observed at  $\delta$  232.53 and is a triplet with  $^1J(^{103}\text{Rh}, ^{13}\text{C}) = 46$  Hz. The equivalent terminal carbonyl occurs as a doublet at  $\delta$  190.18 with  $^1J(^{103}\text{Rh}, ^{13}\text{C}) = 84$  Hz.

## Cadmium and Mercury

Direct observations are relatively easy for both isotopes of cadmium with  $^{113}\text{Cd}$  having a small advantage on receptivity. In recent years, direct measurements of  $^{199}\text{Hg}$  using multinuclear FT systems have produced a wealth of data, some of which are summarized in Table 18. The most relevant problem with  $^{199}\text{Hg}$  observation is excessive line-width. It has been found that  $^{199}\text{Hg}$  resonances at 4.7 T are severely broadened by shielding anisotropy relaxation. Many researchers have used external neat dimethylmercury as a chemical shift reference or as a concentrated sample for the initial search for the  $^{199}\text{Hg}$  reference. In fact dimethylmercury has several intrinsic properties that are well suited for  $^{199}\text{Hg}$  experiments (rapid and accurate measurements, strong coupling with proton), but is very toxic ( $\text{LD}_{50}$  MeHg, 0.1 ml). For this reason mercury perchlorate has been also reported in literature as reference. At a concentration of  $0.1 \text{ mol l}^{-1}$  in a  $0.1 \text{ mol l}^{-1}$  perchloric acid solution the chemical shift is  $-2250$  ppm, relative to dimethylmercury.

**Table 18**  $^{113}\text{Cd}$  and  $^{199}\text{Hg}$  chemical shifts (solution) for selected organometallic complexes

Complex	$\delta_M$ (ppm)
$\text{Cd}(\text{alkyl})_2$	641–434
$\text{CdPh}_2$	329
$\text{CdMe}(\text{OR})$	382–258
$\text{CdMe}(\text{SR})$	610, 597
$[\text{Cd}(\text{CN})_4]^{2-}$	510
$\text{HgMe}_2$	2255 (neat liquid)
$\text{HgEt}_2$	1964 (neat liquid)
$\text{HgPh}_2$	1504 ( $\text{CHCl}_3$ )
$\text{Hg}(\text{CH}_2\text{COR})_2$	1485
$\text{Hg}(\text{Vi})_2$	1612 (neat)
$\text{Hg}(\text{C}_6\text{F}_5)_2$	1333 (acetone)
$\text{Hg}(\text{CF}_3)_2$	577 (THF)

Vi = vinyl.

Linear organomercurials provide a convenient basis for the investigation of the effect of substitution in the organic moiety on the metal chemical shift. Increase in the shielding of  $\sim 150$  ppm are observed for each substitution of Me for a H in  $\text{Hg}-\text{CH}_3$  derivatives, while smaller decreases in shielding ( $\sim 30$  ppm) occur on substitution of  $\beta$ -Hs. Cadmium alkyls show a similar behavior, but for silyl mercury compounds, replacements at both  $\alpha$  and  $\beta$  position results in deshielding.

The first ionization potential of  $[\text{HgCl}(\text{R})]$  which relates predominately to the  $\sigma$ -HgC bond shows a correlation with  $\delta(^{199}\text{Hg})$ . However, increasing the number of  $\beta$ -carbon atoms, which decreases the ionization potential, should increase the electron density on mercury and decrease  $\Delta E$ , both of which would cause deshielding, not shielding. The electron-withdrawing substituent generally increases the shielding. When the substituent effect is transmitted by  $-\text{CC}-$  in  $\text{Hg}(\text{CCR})_2$ , the shielding is roughly in agreement with inductive and mesomeric effects, the electron rich groups such as *tert*-butyl giving the most deshielded resonances.

Of the post-transition metals,  $^{199}\text{Hg}$  has been the subject of the majority of spin-spin coupling reports.

In Table 19 the typical ranges for some coupling constants involving Cd and Hg are reported. In alkylmercury compounds,  $^3J(^{199}\text{Hg}, ^{13}\text{C})$  shows a Karplus type of dependency on the dihedral angle. For a series of  $[\text{Hg}(\text{L})\text{CH}_2\text{C}(\text{OMe})\text{Me}_2]$  the variations in  $^1J(^{199}\text{Hg}, ^{13}\text{C})$  and  $^2J(^{199}\text{Hg}, ^1\text{H})$  closely follow the calculated mutual polarizabilities and it is suggested that changes in the 6s contribution to the Hg-C bond are the main cause of the changes in the magnitude of  $^1J(^{199}\text{Hg}, ^{13}\text{C})$ . The increase in the magnitude of  $^2J(^{199}\text{Hg}, ^1\text{H})$  and  $^1J(^{199}\text{Hg}, ^{13}\text{C})$  in organomercurials with the donor ability of the solvent is generally interpreted in terms of coordination. The same order is observed for both poor and

**Table 19** Ranges of some spin–spin coupling constants for Cd and Hg organometallic compounds

<i>J</i>	Complex type/ligands	Range (Hz)
$^2J(^{113}\text{Cd}, ^1\text{H})$	Alkyls	49–90
$^1J(^{113}\text{Cd}, ^{13}\text{C})$	Alkyls, CN	271–1060
$^3J(^{113}\text{Cd}, ^1\text{H})$	Alkyls	6–70
$^nJ(^{113}\text{Cd}, ^{13}\text{C})$	Alkyls	17–45
$^2J(^{199}\text{Hg}, ^1\text{H})$	Alkyls	94–265
$^3J(^{199}\text{Hg}, ^1\text{H})$	Organomercurials	38–311
$^1J(^{199}\text{Hg}, ^{13}\text{C})$	Alkyls, aryls, CN	264–3875
$^2J(^{199}\text{Hg}, ^{13}\text{C})$	Alkyls, aryls	24–920
$^3J(^{199}\text{Hg}, ^{13}\text{C})$	Alkyls, aryls	93–205
$^2J(^{199}\text{Hg}, ^{19}\text{F})$	Vinyls, alkyls	338–1911
$^1J(^{199}\text{Hg}, ^{31}\text{P})$	PR <sub>3</sub>	1980–12 970

intermediate mercury acceptors, and so far the latter does not correspond to the behavior of  $\delta(^{199}\text{Hg})$ . In bis-fluoroalkyl mercury derivatives  $^2J(^{199}\text{Hg}, ^{19}\text{F})$  decreases as the donor ability of the solvent increases.

In  $\text{CdMe}_2$ ,  $^2J(^{113}\text{Cd}^1\text{H})$  is positive, but  $^3J(^{113}\text{Cd}^1\text{H})$  has the opposite sign. Although  $^2J(^{199}\text{Hg}^1\text{H})$  is negative in alkyl derivatives of mercury it is positive in vinyl derivatives. Couplings to  $^{19}\text{F}$  in  $\text{Hg}-\text{CF}_3$  compounds have the opposite sign to those to  $^1\text{H}$  in the analogous  $\text{Hg}-\text{Me}$  system.

## Introduction

Food materials exhibit a wide range of states of complexity. These range from homogeneous and relatively simple mixtures, as in edible oils, to quite complex heterogeneous systems, as in meat or bread (in the latter case both air and heterogeneous solid

phases are present). This range of physical states and chemical compositions requires a wide palette of nuclear magnetic resonance (NMR) techniques and approaches for obtaining in-depth information and characterization of various foodstuffs. NMR techniques are versatile and can provide different types of data and information on the same sample, depending on the experimental parameters selected. The applications include qualitative and quantitative analysis monitoring of processes or biochemical reactions determination of the structure of isolated compounds, the mobility and state of fat and water, the microstructure and aggregation state of various components in foodstuffs, as well as macroscopic imaging with all the advantages of obtaining cross sections without the need for cutting the sample. In terms of quantifying various compounds, NMR spectroscopy has the ability to provide the global concentration of the sample and not only the surface concentration. The disadvantages of the early days of NMR spectroscopy such as 'low sensitivity' or 'expensiveness' of the instrumentation do not hold true in the early twenty-first century. Thus, the modern hardware, software, automation, and hyphenation have reduced the experimental time to a few minutes even for two-dimensional (2D) experiments and increased the sensitivity, allowing easy detection of compounds at levels of micrograms and even nanograms. Moreover, there are arguments supporting the fact that sometimes well established techniques like gas chromatography (GC)–mass spectrometry (MS) produce false results, several of the 'new' compounds reported based on these techniques being in fact experimental artifacts resulting from the decomposition of some original labile compounds in foodstuffs. In such cases NMR has the great advantage of providing information on the studied compounds under ambient conditions of temperature and pressure.

## High Resolution (HR) NMR (Frequency Domain NMR)

Most HR NMR food sciences analyses are done in solution. However, the information provided by HR solid-state NMR is also very valuable for food sciences. Thus it is very likely that in the near future we will see a more balanced number of liquid- and solid-state NMR studies in food sciences.

### Elucidating the Structure of Isolated Compounds

HR NMR is currently the most powerful technique for elucidating the structure of isolated compounds in solution. There are numerous papers describing

the determination of the structure of various compounds isolated from all types of foodstuff. This application is an essential tool in advanced food research and requires prior isolation and purification of the compound under study.

As this approach is identical to that employed in synthetic chemistry, we would not cover it in this article. The interested reader will find extensive coverage of NMR techniques for structure determination in other articles of this encyclopedia.

The following sections will provide examples of applications of various NMR techniques to mixtures of compounds in various food matrices or fluids.

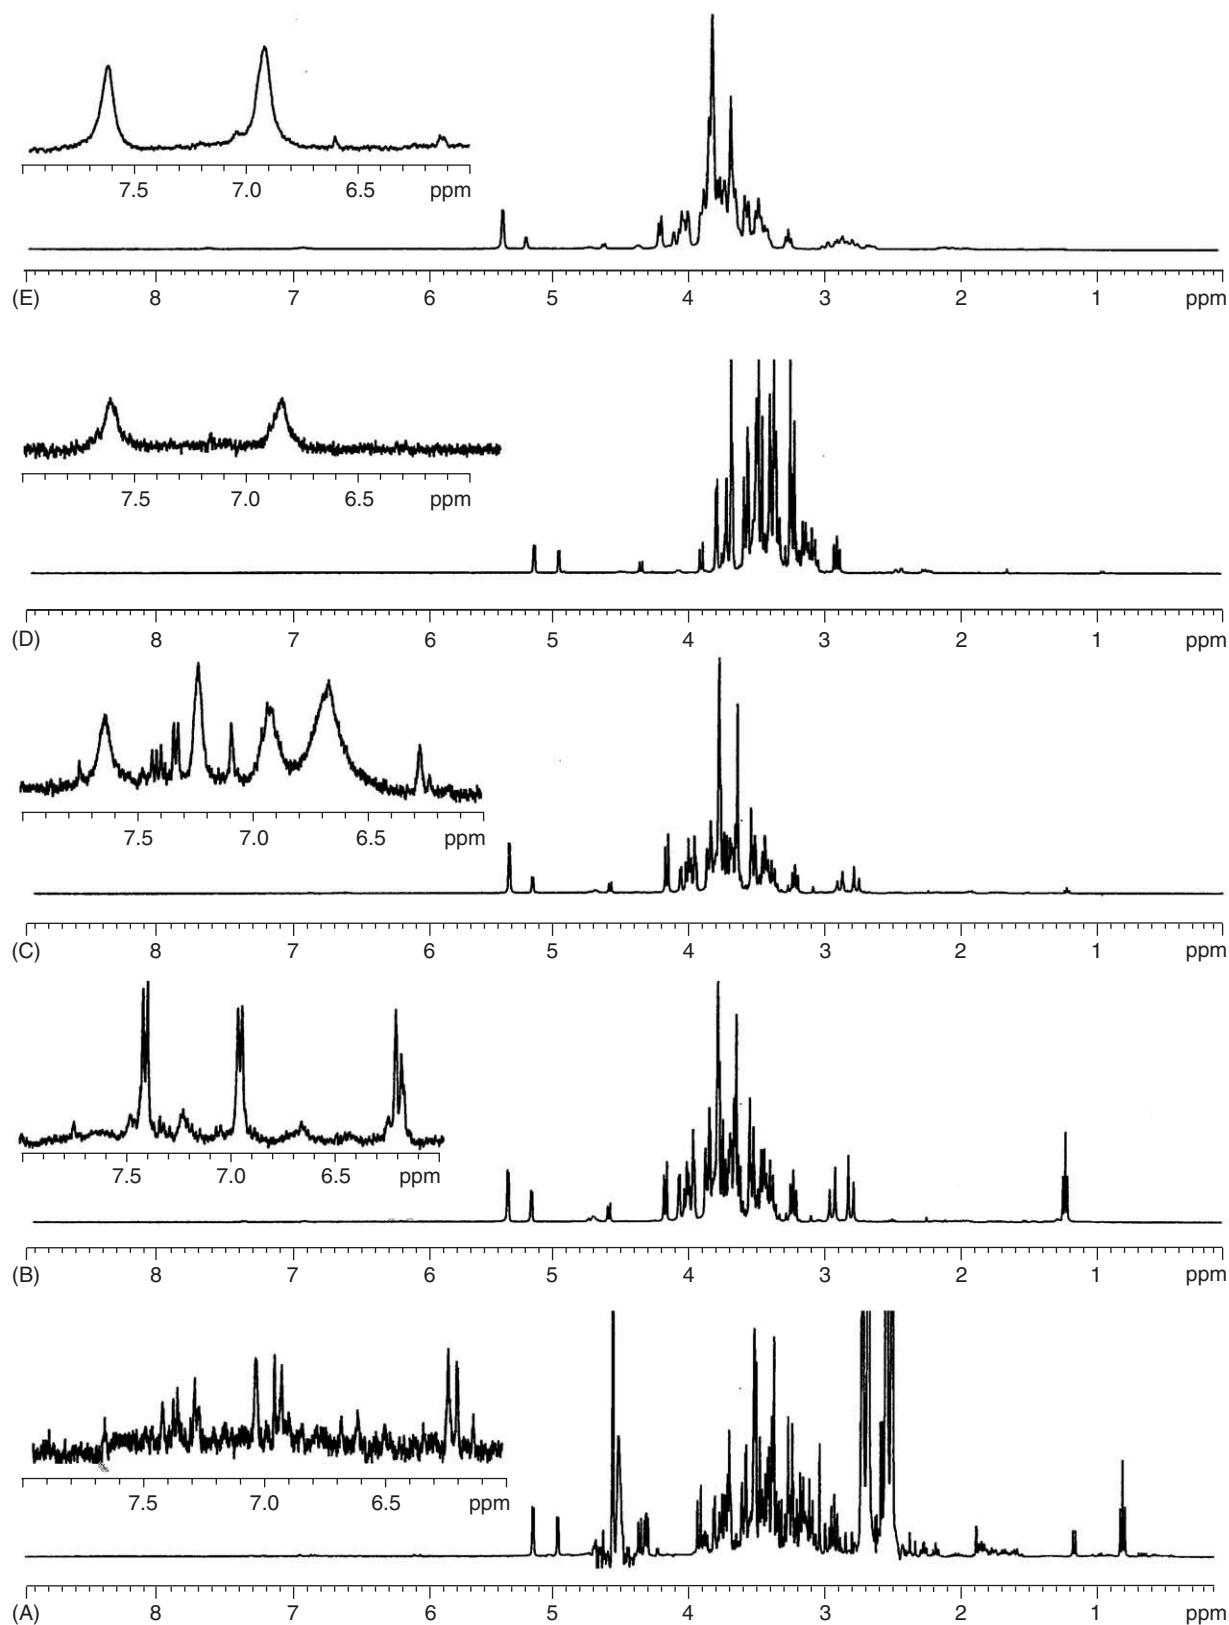

### Fruits and Fruit Juices

$^1\text{H}$ -NMR spectra for various fruit juices have been published, and signals have been assigned to sugars, amino acids, and other compounds like alcohols, acids, and polyphenols. Furthermore,  $^1\text{H}$ -NMR spectra have been used in combination with chemometric techniques for discriminating between apple varieties and for detecting adulteration of orange and apple juices. There are several non-NMR methods classically employed for determination of fruit juice adulteration (density, total amino acids, flavonoid and carotenoid composition). Some of these methods (e.g., liquid chromatography (LC)) require however standards of the suspected markers that are not always available. Moreover, with the classical methods one should preselect the most likely markers for a particular sample based on an educated guess on the expected type of adulteration. HR NMR has the advantage of offering a global profile. Thus, even without a total assignment of signals, in conjunction with chemometric techniques the method can discriminate between various patterns.

Figure 1 shows examples of  $^1\text{H}$ -NMR spectra for some common fresh fruit juices.

The typical profile of the  $^1\text{H}$ -NMR spectrum of fruits and fruit juices could be rationalized by considering three regions. Between 0.5 and 3 ppm there are various signals generated by amino acids, other carboxylic acids, and alcohols. Between 3 and 5.5 ppm the NMR spectrum is dominated by sugars as well as by the residual water signal (4.8 ppm). Although other compounds give rise to some signals in this region, in most cases these signals are of little practical use as they are overlapped by the sugar signals. The region between 5.5 and 10 ppm exhibits signals generated by aromatic and heterocyclic compounds, formic acid, and aldehydes.

Solid-state  $^{13}\text{C}$ -NMR has also been used to study fruits, for instance to follow changes in the cell wall polymers during ripening.

**Figure 1**  $^1\text{H}$ -NMR spectra (400 MHz) for some common fresh fruit juices. (A) lemon juice; (B) grapefruit juice; (C) orange juice; (D) apple juice; and (E) apricot pure.

## Vegetables

The assignment of many components in the  $^1\text{H}$ -NMR spectrum of tomato juice has been published recently. The  $^1\text{H}$ -NMR profile of tomato juice resembles that of fruit juices, with the same distinct zones, i.e., aminoacids, sacharides, and aromatic compounds.

$^1\text{H}$ -NMR spectra of methanolic extracts of control and genetically modified varieties of tomatoes have been analyzed using chemometric techniques. It was possible to assess variations in several metabolites.  $^1\text{H}$ ,  $^2\text{H}$ , and  $^{13}\text{C}$  solid-state magic angle spinning (MAS) NMR spectra have been recorded for tomato skin and potato tissue, providing information on the structure and dynamics of the cuticle polyesters.

It has been demonstrated that for the case of some flavor compounds present in garlic, NMR is superior to GC-MS as the latter produces false results due to the decomposition of some labile compounds.

Large differences in the ratio between proteins and polysaccharides in various mushroom strains have been observed using  $^{13}\text{C}$  solid-state MAS NMR spectroscopy.

## Wine

Surprisingly, in contrast with the early success of  $^2\text{H}$ -NMR spectroscopy in wine analysis (see Wine section of SNIF-NMR),  $^1\text{H}$ -NMR has not been used on whole wine samples until very recently. Although the possibility of quantifying methanol in wine was proved in the early 1990s, it was only a decade later that the field took off, with many minor compounds identified in whole wine samples and with chemometrics helping to rationalize the global profile of the  $^1\text{H}$ -NMR spectrum of wine samples. The same trend is paralleled with spectra for other alcoholic beverages like beer.

Recently an interesting application used a home-made spectrometer based on a 310 mm bore magnetic resonance imaging (MRI) instrument operating at 2 T to record  $^1\text{H}$ - and  $^{13}\text{C}$ -NMR spectra of intact unopened wine bottles. Thus, NMR was able to detect spoiled bottles with acetic acid developed in them without opening them. The application could be very valuable for old and expensive wines.

## Sugars (Carbohydrates)

There are many studies involving  $^1\text{H}$ - and  $^{13}\text{C}$ -NMR spectroscopy of carrageenans, a family of polysaccharides with the structure of linear sulfated galactans. They are extracted from certain species of red seaweed and have been used for a long time as natural texturing ingredients in the food industry.

The polysaccharide  $\beta$ -glucan has been proved to induce beneficial effects such as immunobiological,

hypcholesterolemic, and hypoglycemic effects.  $\beta$ -Glucan is isolated from yeast, and the established wet analytical methods are quite tedious.  $^1\text{H}$ -NMR has been proved to be a rapid alternative method.

Sugars have been determined using both liquid- and solid-state NMR in fruits, vegetables, and their juices, as well as in honey.

Starch products and glycogen have been studied extensively using  $^1\text{H}$ -,  $^{13}\text{C}$ -, and  $^{31}\text{P}$ -NMR spectroscopy. NMR spectroscopy has been used for determining the degree of polymerization, the average number of glucose units, the branching degree, and the anomer distribution of the reducing sugars. The interaction of starch with water and the mobility of polysaccharide chains have been investigated through one-dimensional (1D) and 2D solid-state NMR experiments. The mobility of 'freezable' and 'unfreezable' water in starch was studied using  $^1\text{H}$  and  $^2\text{H}$  solid-state NMR. The aging (retrogradation) of starch has been studied using cross polarization magic angle spinning (CPMAS)  $^{13}\text{C}$ -NMR.

Figure 2 presents the  $^1\text{H}$ -NMR spectrum of glucose. As always, in solution glucose is formed by a mixture of  $\alpha$ - and  $\beta$ -anomers. The spectrum emphasizes the region between 3.2 and 4.0 ppm, which is very crowded in the case of saccharides, glucose being only one of the saccharides present in various foodstuffs. Thus, many food products (including fruits, vegetables, honey, and wines) exhibit an NMR spectrum crowded with signals in the saccharide region.

## Tea

Several flavonoids isolated from tea have been analyzed and their structure determined using NMR. There are several problems with the classical methods of analysis of flavonoids in tea. Due to the presence of complex mixtures of flavonoids in tea, they are often characterized as 'total polyphenols'. The colorimetric method for analysis of total phenols can interfere with other reducing compounds. LC can well resolve peaks for individual flavonoids; however, there are only a few standards available commercially, making the assignment of peaks uncertain in many cases. Thus, the structure of flavonoids giving rise to peaks in LC is often determined using various 1D- and 2D-NMR experiments.

## Coffee

The early NMR studies of coffee were limited to elucidating the structure of isolated compounds.

Several of the major constituents of espresso coffee have been identified in the  $^1\text{H}$ -NMR spectrum.  $^1\text{H}$ -NMR data in combination with chemometrics

**Figure 2** The  $^1\text{H}$ -NMR spectrum of a mixture of  $\alpha$ - and  $\beta$ -glucose in  $\text{D}_2\text{O}$  recorded at 400 MHz. The high peak at 4.8 ppm is the residual water signal.

have been recently used for verifying the authenticity of instant coffees from various producers.

### Milk and Dairy Products

The water-methanol extracts of cheese have been analyzed using  $^1\text{H}$ -NMR, and assignments of several amino acids were done using 2D spectra. Variations in the content of amino acids were observed as a function of ripening time and distance from the center of the cheese wheel. The fatty acid triglycerides from milk have been analyzed using both  $^1\text{H}$ - and  $^{13}\text{C}$ -NMR.

Liquid state  $^{31}\text{P}$ -NMR has been employed since a long time back for studying milk and casein. Solid-state  $^{31}\text{P}$ -NMR has been used for studying the nature of micelles and the interaction between compounds that form them.

### Cereals and Bread

Solution-state  $^{13}\text{C}$ -NMR and  $^{31}\text{P}$ -NMR have been employed in the study of lipids from corn suspension cells. Corn cells have also been grown in the presence of  $^{13}\text{C}$ -enriched acetate for following its incorporation into oleates and linoleates.

Solid-state CPMAS  $^{13}\text{C}$ -NMR has been used for investigating changes in maize and sorghum proteins on wet cooking and popping.

The hydration of proteins from wheat seeds has been studied using solid-state  $^{13}\text{C}$  CPMAS and  $^1\text{H}$

high resolution magic angle spinning (HRMAS) NMR spectroscopy.

### Fats and Oils

Edible fats and oils are ideal candidates for HR NMR. Their good solubility in organic solvents makes the NMR analysis fast, easy, and accurate. Issues such as the composition of fatty acids in oils and fats, adulteration with cheaper oils (especially in the case of extra virgin olive oil), degradation of oils and fats in time and at elevated temperatures, and content of fatty acids in single intact seeds (for breeding purposes) have been studied using NMR. NMR method has some advantages over other methods. Thus, there is no need for sample manipulation before the analysis, information on the distribution of the fatty acid chains in the glycerol moiety (position 1/3 versus 2) is available, and the analysis has a relatively high speed (even for  $^{13}\text{C}$ -NMR, results being obtained within minutes).

A typical  $^1\text{H}$ -NMR spectrum for sunflower oil is presented in **Figure 3**.

A typical  $^{13}\text{C}$ -NMR spectrum for the same sunflower oil is presented in **Figure 4**.

**Figure 5** presents details of the region 172–174 ppm in the  $^{13}\text{C}$ -NMR spectrum (100 MHz), illustrating the power of the method in assigning the distribution of fatty acids in the positions 1/3 and 2 of the glycerol moiety, based on the signals of the CO groups.

**Figure 3**  $^1\text{H}$ -NMR spectrum (400 MHz,  $\text{CDCl}_3$ ) of a sample of sunflower oil.

**Figure 4**  $^{13}\text{C}$ -NMR spectrum (100 MHz,  $\text{CDCl}_3$ ) of a sample of sunflower oil.

If for most food applications, recording the NMR spectra at the highest available magnetic field strength is a great advantage, for edible oils and fats there is not much improvement on passing from 300 to 600 MHz. In this case, the same types of groups from different long chain fatty acids produce similar signals in the  $^1\text{H}$ -NMR spectrum. This fact makes the routine medium-field (300–400 MHz) NMR spectrometers suitable and very competitive (in terms of price-to-quality ratio) for research and quality control of edible oils.

Individual fatty acids and esters have been used as model compounds for assignment of signals in the

NMR spectra of edible oils and fats. The concentration dependence on chemical shifts of model triglycerides has also been explored. Several papers deal with authentic edible oil samples, with reference to both assignment of NMR signals and authentication issues. As expected, many papers deal with NMR of olive oils due to the high market value of the virgin and extra virgin qualities. A lot of effort is put in authentication and determination of the origin of olive oils in connection with the Denomination of Protected Origin. Papers also deal with the identification of mono- and diglycerides in edible oils, as well as other compounds like phenolic derivatives.

**Figure 5** Enlargement of the carbonyl region in the  $^{13}\text{C}$ -NMR spectrum (100 MHz,  $\text{CDCl}_3$ ) of a sample of sunflower oil.

Polyunsaturated fatty acids (PUFAs), characteristic of fish lipids but also present in small quantities in vegetable oils, have been also investigated using NMR. Apart from the composition in fatty acids or minor compounds, the CH region in  $^1\text{H}$ -NMR, and the  $\text{CH}_2$  region in  $^{13}\text{C}$ -NMR have been used for determining the iodine value. Several studies deal with issues like the changes induced in the composition of oils by oxidation, heating, or hydrogenation.

### Seeds

$^{13}\text{C}$ -NMR spectra of intact seeds allow the identification and quantitation of the main fatty acids.

Solid-state  $^{13}\text{C}$  HRMAS and distortionless enhancement by polarization transfer (DEPT) MAS NMR also have been used for studying integral seeds. Thus, the three major components, fats, carbohydrates, and proteins (including the position of the fatty acid in glycerol) could be identified and quantified.

*In vivo*  $^{31}\text{P}$ -NMR has been used for studying the metabolites during the ripening and drying of seeds.

### Fish

Fish oils have been extensively investigated using  $^1\text{H}$ - and  $^{13}\text{C}$ -NMR. PUFAs, important in diet, are believed to reduce the risk of cardiovascular diseases. NMR analysis of PUFA is an interesting alternative to the widely used GC and GC-MS techniques when artifacts may arise either during transesterification or within the GC-MS equipment due to elevated

temperatures. PUFAs are markers for the fish species, age, freshness, storage, and processing conditions.

### Meat

$^{13}\text{C}$  solid-state HRMAS NMR studies have been carried out on cartilages.

$^{31}\text{P}$ -NMR spectroscopy studies of energy-related metabolites have been carried both in HR NMR instruments as biopsies and in MRI instruments as entire muscle pieces. The phosphorus metabolites are directly linked to meat quality. The influence of the stunning method on the postmortem energy metabolism and meat quality has been explored using  $^{31}\text{P}$ -NMR. The pH has been determined using  $^{31}\text{P}$ -NMR and associated with the meat quality. Although the pH is measured routinely through voltammetry, the NMR method has the advantage of measuring the pH in an inner part of the sample, being able to assess it both intra- and extracellularly, as well as *in vivo*.

### Eggs

The oxidation of cholesterol in egg powder has been detected using  $^1\text{H}$ -NMR.  $^{31}\text{P}$ -NMR spectroscopy has been used to quantitate phospholipids in egg lecithin.

### Essential Oils

Essential oils are important flavors and aromas. Many individual compounds have been isolated and characterized. Unseparated mixtures forming essential oils have also been analyzed using  $^{13}\text{C}$ -NMR.

### Agricultural Chemistry

It has been shown that even with medium-field NMR spectrometers (300 MHz), quantitative  $^1\text{H}$ - and  $^{31}\text{P}$ -NMR can rival with chromatography as an analytical method for agricultural chemicals. The advantage of the NMR is that it does not require a reference standard as is the case with chromatography. The possibility of detecting organophosphorus insecticide residues in crops using  $^{31}\text{P}$ -NMR has been demonstrated. Soil samples have been analyzed using  $^1\text{H}$ ,  $^{13}\text{C}$ , and  $^{31}\text{P}$  solid-state and solution-state NMR experiments.

### Plant and Cell Metabolism and Other Biotransformation

The metabolism of plants has been followed extensively using various NMR techniques, employing  $^1\text{H}$ ,  $^{31}\text{P}$ , and  $^{13}\text{C}$  nuclei. All kinds of samples, cells, tissues, and extracts, both *in vivo* and *in vitro*, have been investigated. A special hardware design is used for following biotransformations *in vivo*. Thus the living material is suspended in a culture medium in the NMR tube and air is bubbled through a capillary tube to maintain life.

### $^2\text{H}$ -NMR (Site Specific Natural Isotope Fractionation Using NMR (SNIF-NMR))

$^2\text{H}$  SNIF-NMR is a high-resolution technique. However, the success of this technique in food sciences, together with the large number of published papers, justifies treating it under a separate section.

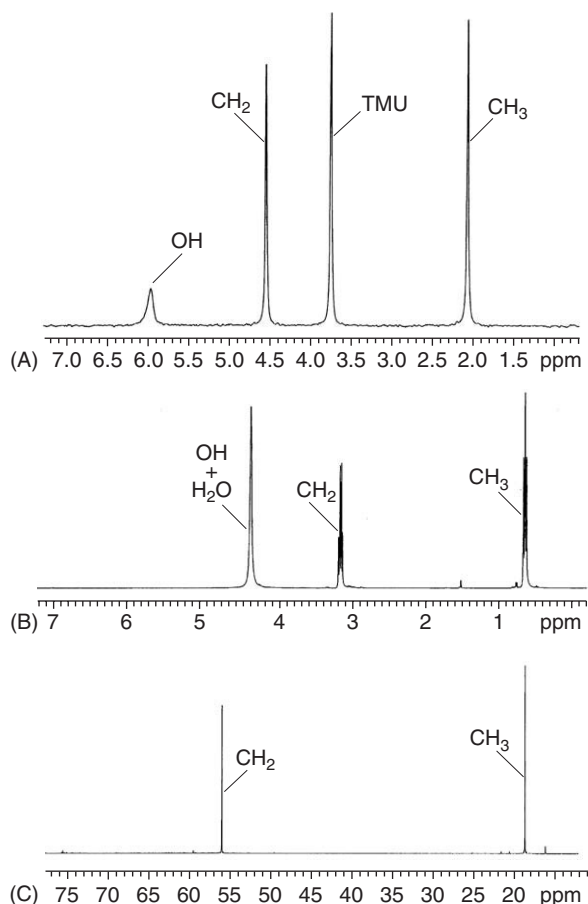

### Wine

Wine analysis using  $^2\text{H}$ -NMR is one of the major applications of NMR in food sciences, probably the most important application of HR NMR.

The basis for authentication of the geographic origin of wine and for spotting its adulteration is deuterium ( $^2\text{H}$ ) NMR spectroscopy. The method developed in the early 1980s by Gerard J. Martin is known as SNIF-NMR. The method was adopted by the French government and later as an official method by the EU and by the Office International de la Vigne et du Vin. SNIF-NMR was registered as a trademark by Eurofins Scientific (Nantes, France).

The principle of the method consists in comparing the ratios of the signals from the  $\text{CH}_3$  and  $\text{CH}_2$  groups of the ethanol molecule in the  $^2\text{H}$ -NMR spectrum. The method requires prior distillation of the ethanol from wine. The power of the method relies on the fact that the  $^2\text{H}/^1\text{H}$  ratio in various

positions of an organic molecule depends on factors such as the plant metabolism (thus bearing information on the type of sugar that by fermentation produces the ethanol) and the isotopic composition of the ground and rain water (thus bearing information on the geographic position). The isotopic ratio  $^2\text{H}/^1\text{H}$  in water varies on Earth between 90 and 160 ppm, depending on the latitude, with the highest values at the equator. It has been proven that deuterium in the  $\text{CH}_3$  site of the ethanol molecule comes from sugars, whereas deuterium in the  $\text{CH}_2$  site comes mainly from water. Thus, in the end, the isotopic ratio  $^2\text{H}/^1\text{H}$  in different sites of the distilled ethanol bears complex information related to the grape type, geographical origin, climate, production year, added sugar, or added water. In order to improve the power of the method, the isotopic composition in the two sites is no longer expressed as a relative ratio but as an absolute ratio, calibrated against a standard of known isotopic composition. The currently official standard is *N,N*-tetramethylurea (TMU). Typically fields of

**Figure 6** HR NMR spectra of ethanol recorded at 9.4 T. (A)  $^2\text{H}$ -NMR (61 MHz); (B)  $^1\text{H}$ -NMR (400 MHz); and (C)  $^{13}\text{C}$ -NMR (100 MHz).

400 or 500 MHz are used in routine analysis; however, owing to the good separation of deuterium signals, 300 MHz instruments can equally provide reliable results.

Figure 6 presents the  $^2\text{H}$ -NMR spectrum of ethanol, employed in the SNIF-NMR method, and for comparison the  $^1\text{H}$ - and  $^{13}\text{C}$ -NMR spectra.

SNIF-NMR is also applied to a whole range of alcoholic beverages, including: cognac, whisky, beer, and grape must.

### Fruit Juices

SNIF-NMR is already a well established technique for fruit juices, being suitable for tracing both their geographical origin and adulteration. The method was originally based exclusively on  $^2\text{H}/^1\text{H}$  analysis, but later its discrimination power was greatly increased by using it in combination with  $^{13}\text{C}/^{12}\text{C}$  analysis through isotopic ratio mass spectrometry (IRMS). In the case of fruit juices SNIF-NMR is mostly used for detecting adulteration with cheaper sugars, being accepted as an Association of Official Analytical Chemists (AOAC) method.

### Miscellaneous Applications of SNIF-NMR

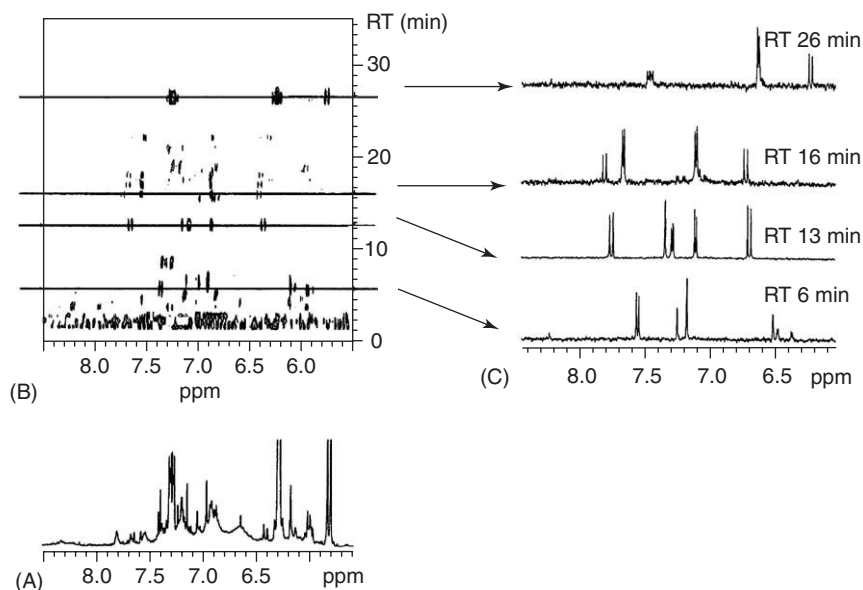

Apart from wine and juices the method has been successfully applied to issues such as the authentication of sugars of various origins, origin of glycerol (sugar fermentation versus edible oil transesterification),

natural versus synthetic origin of aromas, various essential oils, terpenoids, and others. There is a clear legislative discrimination between 'chemically identical' and 'natural' food aromas and flavors, the 'natural' ones being premium products. Owing to the great difference in price between such natural and synthetic aromas, the adulteration techniques became more and more sophisticated. Thus, vanilla adulteration techniques included even the addition of  $^{13}\text{C}$ - and  $^2\text{H}$ -enriched vanillin. Consequently, the analytical methods have had to be improved over the years, and presently combinations of  $^2\text{H}$  SNIF-NMR,  $^{13}\text{C}$  IRMS, and chemometrics applied to several marker compounds in the flavor can successfully cope with the most sophisticated types of adulteration used to date.

### Hyphenated Techniques

Emerging hyphenated techniques have already proved their analytical value and in the near future will certainly become common techniques in food sciences. Commercially available equipment include LC-NMR in both on-flow and stop-flow versions, LC-NMR-MS, LC-NMR-UV-MS, and more recently hyphenation with solid-phase extraction (LC-solid phase extraction-NMR).

Figure 7 illustrates the power of the on-flow liquid chromatography (LC)-NMR technique in the analysis of grape juice.

**Figure 7** On-flow LC-NMR spectrum of a sample of grape juice. ## Low-Resolution (LR) NMR (Time Domain NMR)

LR-NMR is the most commonly used NMR technique to date for quality control in food science and industry, with several official quality control methods in force. The success of the technique is due to several factors, including the power of the method (in terms of information and speed), the early application of the method to foodstuffs, the ecological appeal (no longer needing polluting chemicals), and the relatively low cost of the equipment, making it a very attractive alternative to the tedious wet chemical methods.

### Fats and Oils

Solid fat content (SFC) analysis is probably the most used LR-NMR application in the food industry. The initial success of the method prompted Unilever (manufacturer of margarines and related products) and Bruker (manufacturer of NMR instruments) to start a joint venture with the goal of building a tabletop LR-NMR spectrometer for solid-to-liquid ratio analysis in the fat industry. The method was developed in the early 1970s and over the years led to various quality control protocols for fat and oils that are by now adopted as official methods by various international and national organizations. The success story of SFC analysis opened wide the door for LR NMR methods to penetrate as routine techniques in the food industry.

As the relaxation time depends on the mobility of a particular system (with solids having the shortest relaxation times), it is easy to quantify mixtures using NMR. The bulk magnetization decay (free induction decay (FID)) for samples containing various solid-to-liquid ratios is presented in Figure 8.

**Figure 8** Bulk NMR signal amplitude for samples with various solid-to-liquid ratios. The signal decays exponentially with a constant  $T_2$  relaxation time.

The SFC is a critical parameter for the fats and oils industry. The official American Oil Chemists' Society (AOCS) wet method is dilatometry. Alternative wet methods are differential thermal analysis and differential scanning calorimetry (DSC). LR NMR was proved to be an alternative method for SFC determination in late 1950s. The early continuous wave LR NMR spectrometers rapidly found their way into the fats and oils industry, the method being accepted by the Instrumental Techniques Committee of the AOCS as early as in 1972. Presently the technical choice is radio frequency (RF) pulsed LR NMR. Pulse NMR spectrometers are more compact, very efficient, and relatively cheap. They have the advantage of exciting the protons in the whole sample at once.

The determination of SFC has been extended to oil-in-water emulsions, where additional experimental parameters have to be considered in order to distinguish between oil and water protons. The droplet size of oil-in-water emulsions is usually measured using optical diffraction techniques, but it has also been determined through diffusion NMR experiments.

The degradation of fats and oils during frying has also been determined using LR NMR. During frying oils undergo complex chemical reactions such as oxidation, polymerization, hydrolysis, and isomerization. During these processes polar groups accumulate. The official International Union of Pure and Applied Chemistry and AOAC method for assessing the frying fat quality is the determination of total polar groups through preparative column chromatography. Based on the fact that the relaxation time is decreasing in direct relationship with the amount of polar groups present in the sample, it has been proved that LR NMR data correlate well with the values obtained using the official column chromatography method. The crystallization kinetics of fats is best studied using LR NMR, and as a result most of the published studies follow the crystallization using either LR NMR or DSC.

### Seeds

The wet method for determining fats in seeds is using extraction with organic solvents. LR NMR revolutionized the analysis of seeds, allowing rapid and nondestructive analysis without the need for weighing and drying them. Thus the seeds could be further used for selection in order to improve the genetic capacity of oil production.

The principle of separating and quantifying various components in a system based on the  $T_2$  relaxation time is the following. Various components have various relaxation times mainly due to differences in

**Figure 9** Effect of different drying methods on FID from sunflower seeds. The final moisture content is different when drying takes place at 100°C (A), 60°C (B), or room temperature (C).

mobility (with solids having the shortest relaxation times). For instance, in seeds proteins and carbohydrates relax fast, and they mainly contribute to the first part of the NMR signal, the free induction decay (FID). Water has an intermediate relaxation time, whereas oil has the longest relaxation time. Thus, by carefully selecting the region of the FID where the component of interest is making the major contribution, one can quantify this component relative to other components. Meanwhile the intensity of the signal is proportional to the number of nuclei (protons) generating that signal. Thus by comparing the intensity of FID in the region of the component of interest for different samples or in comparison with a calibrated standard, one can obtain quantitative results. **Figure 9** illustrates how water in various seeds can be quantified with LR NMR when analyzing the middle part of the FID signal. Thus, by drying seeds at room temperature, the quantity of water that remains is higher (and the NMR signal's amplitude is higher) than by drying the same seeds at 60 or 100°C.

An almost identical curve was obtained on drying various seeds (peanut kernels, mustard, sunflower, and soybean) by sun and at 105°C.

When it is desired to quantify the slowly relaxing oil component, a more suitable pulse sequence scheme would be the spin-echo. As illustrated in **Figure 10**, the time at which the second refocusing pulse (of 180°) is applied can be selected so as to obtain an NMR signal generated exclusively by oil. The oil content can be accurately quantified when the amplitude of the signal is compared with a calibration curve generated by standard samples.

### Fruits

LR NMR has been used to determine the changes in water mobility in dehydrated fruits, and the sugar

**Figure 10** The spin-echo RF pulse sequence (A) and its result on the amplitude of the NMR signal (B) when applied to corn samples.

content in intact fruits. The technique is suitable for following the ripening process.

### Sugars (Carbohydrates) and Starch

LR NMR is a routinely used technique for determination of water content in sugars.

Starch hydration, water mobility, and the effect of chemical modification on molecular mobility of starch have also been studied using LR NMR.

Alteration of starch over time (retrogradation) has been studied using LR NMR. Most of the studies employed the  $T_2$  relaxation curves of  $^1\text{H}$ -NMR. Thus it was shown that the number of protons in the solid phase increases with aging, this being explained by the recrystallization of starch.

### Milk and Dairy Products

The state of water in milk, milk powder, casein, whey proteins, and cheese has been investigated using LR NMR.

### Chocolate

LR techniques are routinely used for determination of the fat content and solid-to-liquid ratio in chocolate and cocoa products. Analysis of the fluidification of cocoa butter using LR NMR enabled the identification of cocoas according to the process and the type of roaster used.

## Meat

LR NMR has been widely used in meat studies for quite a long time. There are several advantages associated with NMR, for instance the fact that NMR measures the whole volume of the sample, being less affected by surface effects. The total water and its state in meat (e.g., bounded versus free) can be estimated using LR  $^1\text{H}$ -NMR. This difference is evident on cooling when the free water is freezing, leading to a shortening of  $T_1$  (longitudinal relaxation time). The water holding capacity is an important parameter of meat that could be estimated using NMR. LR NMR has also been correlated with pH and cooking loss using chemometrics. LR NMR is currently a standard method for estimating the total fat content in meat. This way the meat needs not to be dried before the NMR analysis. Types of tissue in calf and cow have been differentiated using  $T_2$  LR NMR of water based on different types of collagen present in various types of tissue. Another important parameter of meat is the development of flavor associated with a long storage time and storage temperature. The so-called warmed-over flavor (WOF) is produced by autoxidation of membrane phospholipids and degradation of proteins and heteroatomic compounds. Some WOFs have been predicted using LR NMR and chemometrics.

## Bread

LR NMR can monitor the distribution and mobility of water during bread making (dough, baking to bread, staling).

The baking process has been performed inside the NMR magnet and followed using the  $^1\text{H}$   $T_2$  relaxation time. The water mobility during storage of bread has been studied using the  $T_1$  and  $T_2$  relaxation curves. The texture parameters (elasticity and firmness) have correlated well with  $T_2$  curves of bread crumbs.

## Potatoes

Prediction of the sensory texture properties of cooked potatoes, based on raw potato analysis, is of major importance to the food industry. The sensory texture quality of potatoes has been predicted using  $T_2$  LR NMR. Correlation of the  $T_2$  LR NMR data with the chemical composition of potatoes has also been performed using chemometrics. Differentiation between potato varieties and determination of dry matter content has also been done using  $T_1$  and  $T_2$  LR NMR.

**Figure 11** MRI cross-sections through a kumquat fruit at 7 T. (Reproduced with permission from Bruker BioSpin, Rheinstetten, Germany.)

## NMR Imaging (Spatial Domain NMR)

The current MRI techniques provide information not only on the internal structure of various foodstuffs but also on the distribution of various compounds (chemical shift imaging), mobility and diffusion of various compounds (like water, oil, or compounds from various packing materials), or dynamic changes like crystallization.

The technique is increasingly being used in food sciences but still less than its true potential. The explanation for the delay in widespread use of NMR imaging techniques in food science and industry is the high cost of the equipment.

**Figure 11** shows four MRI cross-sections through a kumquat fruit. They start from near the surface and advance toward the center of the fruit. The fruit flesh in the centre is surrounded by the peel. The tissue between the fruit flesh and the peel is not visible because of a very short  $T_2$  relaxation time. Spherical structures in the peel are visible, and they contain the typical aromatic contributions of the fruit.

MRI has been applied to various foodstuffs such as meat, cereals, seeds, fruits, vegetables, cheese, or chocolate. The distribution and mobility of various constituents including water, sugars, and lipids have been monitored.

## Introduction

Since conclusions reached in forensic laboratories are used in the criminal justice system, they must leave no room for doubt. Thus, analytical methods must meet strict criteria. They must be extremely selective, reproducible, sufficiently sensitive, and suitable for qualitative and quantitative analysis. It is also highly desirable for the method to call for the minimum number of pretreatment steps and to be applicable to compound mixtures without preliminary separation of their components. Nuclear magnetic resonance (NMR) spectroscopy meets these criteria. It is well

known to be a powerful tool for the elucidation of chemical structures and the identification of organic compounds. It has been used in various types of forensic analysis for many years. It should be stressed that NMR is not used as a stand-alone technique in the forensic laboratory, but in conjunction with many others, including mass spectrometry, infrared (IR) spectroscopy, and various chromatographic techniques.

Some early reports on investigations using NMR spectroscopy for forensic analysis were pessimistic about its application as a routine method. NMR was viewed as an insensitive technique when compared with some of the other methods of analysis; the cost of the instrument was comparatively high and the results obtained required considerable expertise to interpret. This situation no longer exists. During the last several years, the amounts of material required

## Introduction

Since conclusions reached in forensic laboratories are used in the criminal justice system, they must leave no room for doubt. Thus, analytical methods must meet strict criteria. They must be extremely selective, reproducible, sufficiently sensitive, and suitable for qualitative and quantitative analysis. It is also highly desirable for the method to call for the minimum number of pretreatment steps and to be applicable to compound mixtures without preliminary separation of their components. Nuclear magnetic resonance (NMR) spectroscopy meets these criteria. It is well

known to be a powerful tool for the elucidation of chemical structures and the identification of organic compounds. It has been used in various types of forensic analysis for many years. It should be stressed that NMR is not used as a stand-alone technique in the forensic laboratory, but in conjunction with many others, including mass spectrometry, infrared (IR) spectroscopy, and various chromatographic techniques.

Some early reports on investigations using NMR spectroscopy for forensic analysis were pessimistic about its application as a routine method. NMR was viewed as an insensitive technique when compared with some of the other methods of analysis; the cost of the instrument was comparatively high and the results obtained required considerable expertise to interpret. This situation no longer exists. During the last several years, the amounts of material required

for NMR studies have dropped drastically so that most experiments on state-of-the-art equipment require a few tens of micrograms of small molecule organic sample. The advances in NMR technology which gave rise to these huge increases in sensitivity have been driven by the desire to determine the structures of larger molecules, such as proteins. These advances include the development of higher-field magnets (currently up to 900 MHz) and improved probe technology (including the new cryoprobes that give very large sensitivity enhancement by eliminating much of the electrical noise present in normal probes). The costs of the modern mid-field strength instruments (400–600 MHz), which are more than adequate for essentially all forensic work, are comparable to those of other equipment such as mass spectrometers. Most modern spectrometers can be purchased with software which makes the acquisition of data completely automatic. The amount of training required by the forensic analyst for most routine experiments is minimal.

## Sample Types

Because of the diverse areas of investigation carried out by forensic analysts, the types of samples vary greatly. They can be in any form – solid, liquid, or gas. Samples can originate from any source and may be organic, inorganic, natural, or synthetic. They may be present in large quantities or as a minute residue. Illicit drug seizures usually consist of powders, plant materials (or their extracts), or occasionally dosage forms. Sometimes it is only necessary to identify the major constituent of a sample, while for other samples the minor components may be important. The information obtained in the analysis may be used, not only to support a case, but also to provide valuable intelligence information.

Some applications for which NMR has been used in forensic analysis include the identification of compounds by comparison of spectra with those of authentic materials, the determination of structures of unknown compounds such as ‘designer’ drugs, the identification of impurities in illicit drugs, the determination of optical purity of drugs, and the characterization of explosives, accelerants, fire residues, and various body fluids or tissue extracts. This article will briefly review each of these applications.

## Sample Preparation

The procedure used to prepare a forensic sample for NMR analysis depends on its nature and the information required. Because of the wide variety of types

of samples, a number of different procedures are used. In the case of an exhibit that is a ‘pure’ compound, or for which data are required for the total sample, the analyst need only select a suitable deuterated solvent and dissolve an appropriate amount of material for acquisition of required spectra. For any other kind of samples, decisions concerning the information required from the material will determine the method of sample preparation.

The general methodology used in the isolation and determination of illicit drugs from component mixtures depends on the molecular structure of these compounds. It is often possible to select a solvent that effectively dissolves the drug of interest but does not dissolve the other components to any significant degree. Thus, spectral interference from the excipients is eliminated. For example, deuteriochloroform may be used to extract many drugs from formulations in which the excipients consist of sugars, since the sugars will remain in the aqueous phase. When this simple procedure is not applicable, others, which take advantage of the characteristics of the drugs, must be used. Drugs may be divided into four general categories (acidic, basic, amphoteric, and neutral), which have different partition coefficients between immiscible organic and aqueous phases. This occurs because the hydrogen ion concentration (a function of pH) in the aqueous phase often affects the ionic state or polarity of molecules, depending on the functional groups present. Adjustment of the aqueous phase pH allows the separation of drugs from the four different categories. For example, acidic and neutral drugs would be extracted into the organic solvent if the aqueous solution is made acid, while basic and neutral drugs would be extracted from aqueous base. For amphoteric drugs, such as morphine or phenylephrine, the pH must be carefully controlled to be at their respective isoelectric points because the drugs exhibit both acidic and alkaline properties. At the isoelectric point, the molecules exist predominantly in the nonpolar or nonionized form. Neutral drugs may be isolated from the others by extracting an acidic solution with an organic solvent and then washing this solvent with aqueous base.

Other forensic samples require different methods of preparation. Biological fluids often may be analyzed directly, or after the addition of a small amount of D<sub>2</sub>O for signal frequency locking. Plant material, tissue samples, and biological fluids may be put through extraction procedures to obtain samples suitable for NMR analysis. Explosives and accelerant samples may be prepared by normal chemical procedures. Postexplosion residues and fire debris may be extracted, and samples from these extracts prepared in the normal way.

## Applications

### Analysis of Drugs and Related Materials

**Identification of 'known' compounds** The most common application of NMR in forensic analysis is its use in the identification of materials in drug seizures. For this purpose the analyst compares the NMR spectra for the exhibit with those for authentic materials, in much the same way as for IR spectra, allowing the rapid identification of illicit drugs. When the spectra being compared are from spectrometers of different magnetic field strengths, or if they are determined using different solvents or at different concentrations, the analyst must be aware that the appearance of  $^1\text{H}$  spectra may appear to be very different. Because these kinds of differences are usually minor for  $^{13}\text{C}$  NMR spectra (which are also much simpler in appearance than  $^1\text{H}$  spectra), most commercial spectral libraries are for  $^{13}\text{C}$  spectra. However, modern spectrometers allow users to create, maintain, and search their own proton spectral libraries. Also, a number of books are available that contain collections of proton spectra of chemicals of forensic interest.

It is often difficult to obtain matching IR spectra for drugs that possess hygroscopic or polymorphic properties. Also, many drugs fragment in such a manner that their mass spectra are ambiguous and difficult to interpret. It is often difficult to distinguish between positional isomers using mass spectrometry. NMR provides an attractive alternative method of analysis since it avoids these problems, while at the same time allows identification and quantification of drugs in dosage forms.

**Identification of unknown compounds** NMR spectroscopy provides the forensic analyst with one of the most powerful techniques for identification of unknown compounds. The full range of structural elucidation techniques of modern spectrometers is available. First, the analyst obtains a high-resolution proton (NMR) spectrum in an appropriate deuterated solvent. The chemical shifts and integration in the spectrum give an indication of the types (aliphatic, olefinic, aromatic, etc.) and relative numbers of protons present in the molecule. The appearance of the coupling patterns in the molecule often provides very useful structural information. If the identity of the unknown cannot be determined from the results of the  $^1\text{H}$  NMR study alone, the analyst next obtains  $^{13}\text{C}$  information. The  $^{13}\text{C}$  NMR spectrum gives a count of the number of nonequivalent carbon atoms, as well as the types of carbon (aliphatic, aromatic, carbonyl, etc.) present in the unknown. The number of protons attached to each carbon may

be determined by using pulse sequences such as distortionless enhancement by polarization transfer, which are available on all modern spectrometers. If the structure of the unknown is still not determined from these results, the analyst may then turn to more sophisticated techniques such as nuclear Overhauser enhancement (NOE) experiments or various two-dimensional (2D) experiments.

It is crucial for the analyst to determine the exact structure of chemical substances obtained in police seizures. In a number of countries, only the compounds on a specific list are illicit. This has led to the appearance of 'designer' drugs. These are compounds that differ from illicit drugs in the position of substituents or by having had one substituent replaced by another, having an ethoxy group instead of a methoxy, for example. If no authentic samples of these materials are available, it is sometimes difficult to determine which positional isomer of a particular drug is being analyzed. Consider, for example, that for something as simple as ethoxydimethoxyamphetamine (analogs of trimethoxyamphetamines) there are 16 possible isomers. The  $^1\text{H}$  NMR spectrum of each of these compounds would be expected to be distinct. The aliphatic portion of the spectrum should be similar for all isomers. Simple examination of the aromatic portion of the spectra of ethoxydimethoxyamphetamines allows them to be sorted into three sets of isomers – those in which the two aromatic protons are *ortho* (six isomers), *meta* (seven isomers), or *para* (three isomers) to each other. These sets can be distinguished by the magnitude of the observed coupling constants for the aromatic protons,  $J_{\text{ortho}} = 8 \text{ Hz}$ ,  $J_{\text{meta}} = 2 \text{ Hz}$ , and  $J_{\text{para}} = 0 \text{ Hz}$ . All of the isomers in these sets should be easily differentiated by the use of NOE difference spectra. **Figure 1** shows the proton spectrum of the hydrochloride salt of one of the ethoxydimethoxyamphetamines, as well as the aromatic region of some representative NOE difference spectra. The aromatic protons show no coupling ( $J = 0 \text{ Hz}$ ), indicating that they are *para* to each other. This means that the substituents are in the 2-, 4-, and 5-positions. The problem is to determine in which of these positions the ethoxy is located. Irradiation of the high-field methoxy signal produced an NOE for the low-field aromatic signal (**Figure 1B**), while the low-field methoxy gave a similar effect for the high-field aromatic resonance (not shown). Only substituents in the 1- or 5-positions should produce an enhancement for the proton on the 6-position. Since both aromatic protons are affected by irradiation of the two methoxy resonances, the 5-substituent must be a methoxy. Irradiation of the signal for the alkyl methylene (at 2.86 ppm) produced NOE effects for the low-field

**Figure 1** 400 MHz  $^1\text{H}$  NMR spectrum of 4-ethoxy-2,5-dimethoxyamphetamine hydrochloride in  $\text{D}_2\text{O}$  (A) and the aromatic portions of the NOE difference spectra obtained by irradiating the high-field methoxy (B), the alkyl methylene (C), and the ethoxy methylene (D).

aromatic proton, which therefore must be the proton on 6-position (**Figure 1C**). It also gave an effect for the low-field methoxy (not shown), indicating that this methoxy must be in the 2-position. Irradiation of the ethoxy methylene gave rise to an NOE at the high-field aromatic proton (**Figure 1D**). This is the same proton that was enhanced by the methoxy in the 2-position, providing further proof that the ethoxy is in the 4-position. These results clearly illustrate how the structure of this chemical substance can be established as 4-ethoxy-2,5-dimethoxyamphetamine, whose structure is shown in **Figure 1**.

**Quantification** After identifying an illicit substance in a police exhibit, the forensic analyst may also be called upon to provide quantitative results. In many seizures, the drug is 'cut' with other substances. These range from starch or sugars to other drugs. For example, cocaine exhibits are often found to contain drugs such as lidocaine. NMR spectroscopy provides the analyst with a quick method for quantification of illicit substances in their exhibits. This is

done in a straightforward manner using either  $^1\text{H}$  or  $^{13}\text{C}$  spectra acquired under the proper conditions. Using these procedures the analyst can obtain absolute quantitative results for each substance present in the sample, even for fairly complex mixtures. The basic requirement for quantification is that each substance to be studied gives rise to at least one signal that is not overlapped with resonances for other materials.  $^1\text{H}$  NMR provides the quickest method for quantification because of its relative, inherent sensitivity and shorter relaxation times compared to  $^{13}\text{C}$ . However, the much wider chemical shift range and the simpler appearance of the carbon spectrum often make it the method of choice for complex mixtures.

**Impurity profiling** When an NMR spectrum is taken for a seized material, it shows peaks for the impurities as well as for the drug itself. These 'extra' peaks will often allow the identification of one or more of the impurities in the sample. This information can be used for police intelligence operations.

**Figure 2** 200 MHz <sup>1</sup>H NMR spectra of cocaine hydrochloride standard (A) and two police exhibits (B and C).

Knowledge of which impurities, including solvent residues, are present in an exhibit can often be used to determine the synthetic route used to prepare the drug or solvent used for recrystallization. This information may be used to show whether or not various exhibits were from the same source. **Figure 2** shows spectra for cocaine hydrochloride standard (**Figure 2A**) and some police exhibits (**Figures 2B** and **2C**). Note the extra peaks between 3 and 4 ppm and at ~5.2 ppm, which are due to sugars in the exhibits. The presence of lidocaine can be detected in one sample (**Figure 2C**) by the presence of singlet

resonances at ~7.1 and 2.2 ppm and a triplet at 1.4 ppm.

**Optical purity** There are a number of drugs for which only certain optical isomers are illicit, depending on the country. For example, methamphetamine is an illicit drug in Canada, whereas in the USA only the (+)-isomer is controlled. Other common drugs for which only specific isomers are restricted are the methorphans (levomethorphan is an internationally recognized narcotic, whereas the dextromethorphan is a common ingredient in over-the-counter cough

medications) and propoxyphenes (dextropropoxyphene is internationally recognized as a narcotic, while levopropoxyphene, an antitussive, is not). NMR spectroscopy provides a quick and easy method for determining the optical state of drug substances. It should be noted that even in cases where optical isomers are not legislated against, information on the drugs' optical states can still provide some useful information. For example, if a seizure of methamphetamine is found to be racemic or optically pure, this gives valuable intelligence information regarding the starting material and the synthetic route employed in its production.

There are a variety of NMR methods that may be used to determine the optical purity of drugs. These include the use of chiral solvating agents (CSAs), chiral lanthanide shift reagents (CLSRs), and chiral derivatization reagents (CDRs). Each of these reagents has its advantages and disadvantages, depending on the drug being studied and the field strength of the spectrometer available to the analyst. The CLSRs work best at lower fields because the line-broadening caused by these reagents increases as the square of the field strength. Normally, CSAs and CDRs do not produce as much resolution of optical isomer signals as the CLSRs. However, the CSAs and CDRs do not cause line-broadening and may be used with high-field spectrometers where better resolution is obtainable. Figure 3 shows some typical spectra for the methyl of a racemic amphetamine sample alone (Figure 3A), in the presence of tris[3-(trifluoromethylhydroxymethylene)-(+)-camphorato] europium(III) derivative (Figure 3B) and in the presence of *R*(+)-1,1'-bi-2-naphthol (Figure 3C). Also shown is the methyl resonance for the 2,3,4,5-tetra-*O*-acetyl-beta-D-glucopyranosyl isothiocyanate (GITC) derivative of amphetamine (Figure 3D). These spectra illustrate typical separation of signals for optical isomers obtained by each of these methods.

### Novel Applications of NMR in Forensic Analysis

**Arson investigations** The use of  $^1\text{H}$  NMR spectroscopy has been reported to complement the results of other methods for analyzing debris from suspected arson cases. The type of accelerant used to start the fire can be identified by the relative sizes and shapes of the peaks in different regions of the NMR spectrum – the strictly aliphatic portion from 0 to 2 ppm, the aliphatic moieties attached to aromatic components from 2 to 3 ppm, and the aromatic region from 6.5 to 7.5 ppm. Thus, paint thinner, lighter fluid, kerosene, diesel fuel, and various brands of gasoline all give their own unique patterns. These patterns

**Figure 3** 200 MHz  $^1\text{H}$  NMR spectra of the methyl signals for racemic amphetamine alone (A) and in the presence of the tris[3-(trifluoromethylhydroxymethylene)-(+)-camphorato] europium(III) derivative (B) and *R*(+)-1,1'-bi-2-naphthol (C). 400 MHz spectrum of the methyl group of the 2,3,4,5-tetra-*O*-acetyl-beta-D-glucopyranosyl isocyanate derivative of racemic amphetamine (D).

were found to be relatively unchanged when the petroleum distillates were weathered, burned, or steam distilled. Even with the low-field instruments used for these studies, distinctions between accelerants within a class could be accomplished. Certainly, especially with the increased sensitivity and resolution of the more modern high-field instruments, NMR spectroscopy could provide the arson analyst with a powerful analytical tool that could supplement other current methods of analysis.

**Analysis of explosives**  $^1\text{H}$  NMR spectroscopy has been used to study both unexploded and postexplosion samples for a variety of single explosives and mixtures. It provides a simple, fast, and reliable method of identifying explosive materials, even for mixtures without preseparation. The postexplosion samples were prepared by extracting debris with acetone, removing the solvent, and redissolving the residue in acetone- $d_6$ . These results fully or partially confirmed the results obtained by thin-layer chromatography (TLC) or gas chromatography-mass spectrometry in more than half of the cases studied. The sensitivity of the 250 MHz instrument used was insufficient for detection of the explosive residues in the remainder of the samples. With more modern higher-field instruments this should be less of a problem. In some cases 2,4-DNT and

2,6-DNT (impurities in TNT) were detected by NMR when they had been missed by analysts using TLC. Qualitative and quantitative determinations of small amounts of additives or impurities have been used to differentiate between homogeneous explosives originating from different sources. Characteristic impurities may allow the analyst to determine the synthetic route used to produce the explosive.

**Analysis of body fluids and tissues** Although the use of NMR spectroscopy for the study of body fluids and tissues is now common, it has not been employed frequently for forensic analysis. There have been a few studies of autopsy material extracts that clearly show the potential utility of NMR.  $^1\text{H}$  NMR has been used to identify a number of drugs from autopsy material, whereas  $^{31}\text{P}$  NMR was used quantitatively for postmortem blood, liver, and urine specimens taken from victims who committed suicide using the herbicide glyphosphate. It has also been shown that  $^1\text{H}$  NMR may be used, at least with the rat, to provide information on postmortem biochemical changes in skeletal muscle extracts that may be used to establish the time of death. Forensic analysts have also used NMR in some cases of lethal and nonlethal drug poisoning for identifying and quantitatively analyzing specimens obtained from blood, urine, and stomach contents, even in the presence of drug mixtures.  $^{31}\text{P}$  NMR spectra of gastric content, urine, and serum from poisoned people have been used as a screening tool for a number of organophosphorus pesticides. With modern spectrometers, these compounds are readily detectable in submicrogram quantities in short periods of time.  $^1\text{H}$  NMR has also been used to detect salicylate poisoning by examining the aromatic portion of spectra of urine. It has also been used for identification of persons who have been drinking by quantification of the ethanol content of their saliva.

## Trends in the Use of NMR in Forensic Analysis

NMR spectroscopy will probably continue to play a supporting role in forensic analysis. It will not be used as the primary source of analysis for routine samples, but rather as a powerful tool for solving problems in more unusual cases. It will certainly continue to play a vital role in the identification of unknown compounds such as 'designer' drugs. The ease with which NMR may be used to determine isomeric composition of drugs could make it an attractive method for determining the optical state of illicit drugs where this is a consideration, but the recent advances in chiral chromatographic methods may limit its use in this area. As the number of forensic analysts with knowledge of the enhanced sensitivity, resolution, and capabilities of modern spectrometers grows, there will likely be many new uses for NMR in forensic analysis. The use of NMR in some of the areas discussed above will undoubtedly increase.

## Introduction

Nuclear magnetic resonance (NMR) spectroscopy has been widely used in the pharmaceutical industry for over a quarter of a century for the structure

elucidation of chemical samples, and this remains the main use up to this day. The preeminent position of NMR in this area reflects the fact that it is *the* most powerful tool for the elucidation of molecular structure in solution. Over the past two decades, the use of NMR spectroscopy has grown enormously as a result of the development of: (1) high-field ( $>14.1\text{ T}$ ,  $\approx 600\text{ MHz}$  for  $^1\text{H}$  NMR) superconducting magnets, giving better sensitivity and signal

dispersion (spreading out of the signals) and (2) two-dimensional (2-D), 3-D, and 4-D NMR spectroscopy, giving better signal dispersion and phenomenal capability for determining specific atom-to-atom connectivities, either through space or through bonds, especially in large and complex molecules such as natural products and proteins. As the power of NMR has increased, so has its range of applications within the pharmaceutical industry, especially within the R&D environment. Two particularly important new applications of NMR spectroscopy are: (1) hit-finding against the protein targets that are involved in various disease states, and (2) the study of diseases, their treatment, and of drug safety via the new science of metabolomics. Indeed, nowadays, NMR is increasingly used to solve biological problems, and the technologies used range from biofluid NMR to *in vivo* NMR spectroscopy of perfused organs and whole animals, right through to magnetic resonance imaging (MRI) of whole animals and human beings. This article focuses on the key areas in this huge field of endeavor and is necessarily selective.

## Chemical Samples

### Molecular Structure Elucidation

Structure elucidation is an exercise in which a large number of techniques may be used: NMR spectroscopy on its own will often not be sufficient to solve a problem, at least in an efficient manner. Ultraviolet (UV) spectroscopy gives information on chromophores in molecules, whilst mass spectroscopy (MS) is used to determine the molecular mass and, for compounds with molecular masses less than  $\sim 1000$  Da, the molecular formula, via high-resolution measurements on the molecular ion. In addition, fragmentation patterns in the mass spectrum can often be interpreted in terms of structural features in the molecule. Infrared (IR) spectroscopy provides information on functional groups such as ketone, unsaturated ester groups in the molecule, but NMR spectroscopy remains the only method of structure elucidation in solution that is capable of unambiguously piecing together structural fragments into the final molecular structure. NMR is uniquely powerful in its ability to: (1) elucidate molecular structure, (2) distinguish between isomers, (3) provide information on molecular conformations, and (4) give information on molecular dynamics. These points are best illustrated with examples.

**Natural products** The structure determination of a natural product is often more demanding than that

**Figure 1** Scanning electron micrograph of a novel *Streptomyces* species from which compound (I) and many other related milbemycins have been isolated. (See Baker GH, Dorgan RJJ, Everett JR, Hood JD, and Poulton ME (1990) A novel series of milbemycin antibiotics from *Streptomyces* strain E225. II. Isolation, characterisation, structure elucidation and solution conformations. *Journal of Antibiotics* 43: 1069–1076.)

of a synthetic compound, for which the precursor and synthetic protocol will usually be well defined. **Figure 1** shows a scanning electron micrograph of a novel *Streptomyces* species that produced a series of active anthelmintic (antiworm) metabolites. After isolation, the structure of metabolite (I) was determined unambiguously using a variety of spectroscopic techniques, but principally NMR. Compound (I) possesses a UV maximum at 224 nm, suggesting the presence of a diene chromophore. The high-resolution electron impact mass spectrum shows a molecular ion at  $m/z$  568.3412, which indicates that the molecular formula is  $C_{34}H_{48}O_7$  (theoretical mass 568.3400). The IR spectrum shows the presence of a saturated ester function and alcohol groups. This was the sum total of the information prior to the application of NMR. The 2-D  $^1H$ ,  $^1H$  correlation spectroscopy (COSY)-45 NMR spectrum of (I) (**Figure 2**) gives information on which protons in

**Figure 2** A contour plot of a portion of the 400 MHz 2-D  $^1\text{H}$  COSY-45 NMR spectrum of (I) in  $\text{CDCl}_3$ :TMS. Connectivities between the signals of  $J$ -coupled protons are traced out with horizontal and vertical lines and are labeled. (See Baker GH, Dorgan RJJ, Everett JR, Hood JD, and Poulton ME (1990) A novel series of milbemycin antibiotics from *Streptomyces* strain E225. II. Isolation, characterisation, structure elucidation and solution conformations. *Journal of Antibiotics* 43: 1069–1076.)

the molecule are spin-spin coupled over (usually) two or three bonds. In this case, the experiment was tuned to pick up four- and five-bond couplings as well. The large number of through-bond, atom-to-atom connectivities (Figure 3) for the hydrogen atoms enabled a considerable portion of the structure to be assembled by inspection. However, as often occurs, the fragments of protonated carbon structure that can be assembled (see Figures 3A–3D) are separated from one another by the so-called spectroscopically silent centers: quaternary carbons and heteroatoms (all oxygen in this case). These silent centers possess no hydrogens and thus the chain of proton-to-proton connectivity can be broken. In some cases, including this one, long-range (four- and five-bond) proton-to-proton connectivities are helpful; in others the problem is overcome by

**Figure 3** Map of the four fragments (A)–(D) of proton-to-proton connectivities found for (I) in the 2-D  $^1\text{H}$  COSY-45 spectrum. Key: —  $^2J$ ,  $^3J$ ; - - -  $^4J$ ,  $^5J$  proton-to-proton through-bond connectivities. (See Baker GH, Dorgan RJJ, Everett JR, Hood JD, and Poulton ME (1990) A novel series of milbemycin antibiotics from *Streptomyces* strain E225. II. Isolation, characterisation, structure elucidation and solution conformations. *Journal of Antibiotics* 43: 1069–1076.)

obtaining long-range (two- and three-bond) proton-to-carbon connectivities from 2-D correlation experiments such as heteronuclear multiple bond correlation experiments. Thus, using this long-range connectivity information, compound (I) was shown to be a milbemycin antibiotic with structure (I) as shown in Figure 4. The relative configuration at the chiral centers of (I) was determined by the measurement of stereospecific spin-spin coupling constants ( $J$ -values) and from nuclear Overhauser effect (NOE) experiments. For instance, the large value of the three-bond coupling between H24 and H25 ( $^3J_{24,25} \sim 9.3$  Hz) indicates that the O21–C25 tetrahydropyran ring is in a chair conformation with H24 and H25 *trans*-diaxial or *anti* to one another. The observation of NOEs between H17 and H25 confirmed that these two hydrogens were close in space and thus the stereochemistry of the *spiro* ring fusion. On a modern NMR spectrometer operating at 500 MHz or higher, the entire NMR data collection and analysis exercise could take less than 2 days, with <1 mg of reasonably pure material.

### Conformational Analysis in the Solution State and in the Solid State (Polymorphism)

**Solution state** One goal of medicinal chemistry research is to understand the structural features responsible for the biological activity of drugs. The structure elucidation of a drug substance is an important first step in this process, but equally

**Figure 4** The molecular structure of (I) as determined by NMR: oxygen atoms are shaded and pseudoaxial protons are labeled 'a'.

important is the understanding of the conformation (shape) and dynamics of the molecule. These can be important determinants of drug–receptor interactions and hence of drug activity. NMR spectroscopy is uniquely powerful in its ability to determine detailed aspects of molecular shape and dynamics in both solution and solid. In the solution state,  $J$ -couplings can be analyzed to give information on the conformational populations about single bonds, NOEs can be used to probe close through-space interactions between pairs of protons (or protons and hetero atoms), and, finally, relaxation time measurements are able to give detailed information on molecular dynamics. It is often useful to combine the NMR studies with X-ray crystallographic studies and with molecular modeling calculations. The

macrolide antibiotic erythromycin A provides a good example. **Figure 5A** shows the crystal structure of a salt of erythromycin A. Several features are of interest, including the close cross-ring approach of H4 and H11 in the macrolide ring and the very close approach of the hydrogens of CH<sub>3</sub>-16 to H1'' (<1.5 Å (0.15 nm)). NMR was used to determine whether these conformational features are also present in solution. **Figure 5B** shows a portion of an NOE difference spectrum of erythromycin A after the irradiation of H11. The clear NOE response at H4 shows that these two protons are close together in solution as well as in the solid state. Calculations based on the crystal structure predicted that the rotation of CH<sub>3</sub>-16 would be very restricted due to its proximity to H1''. This feature is also found in

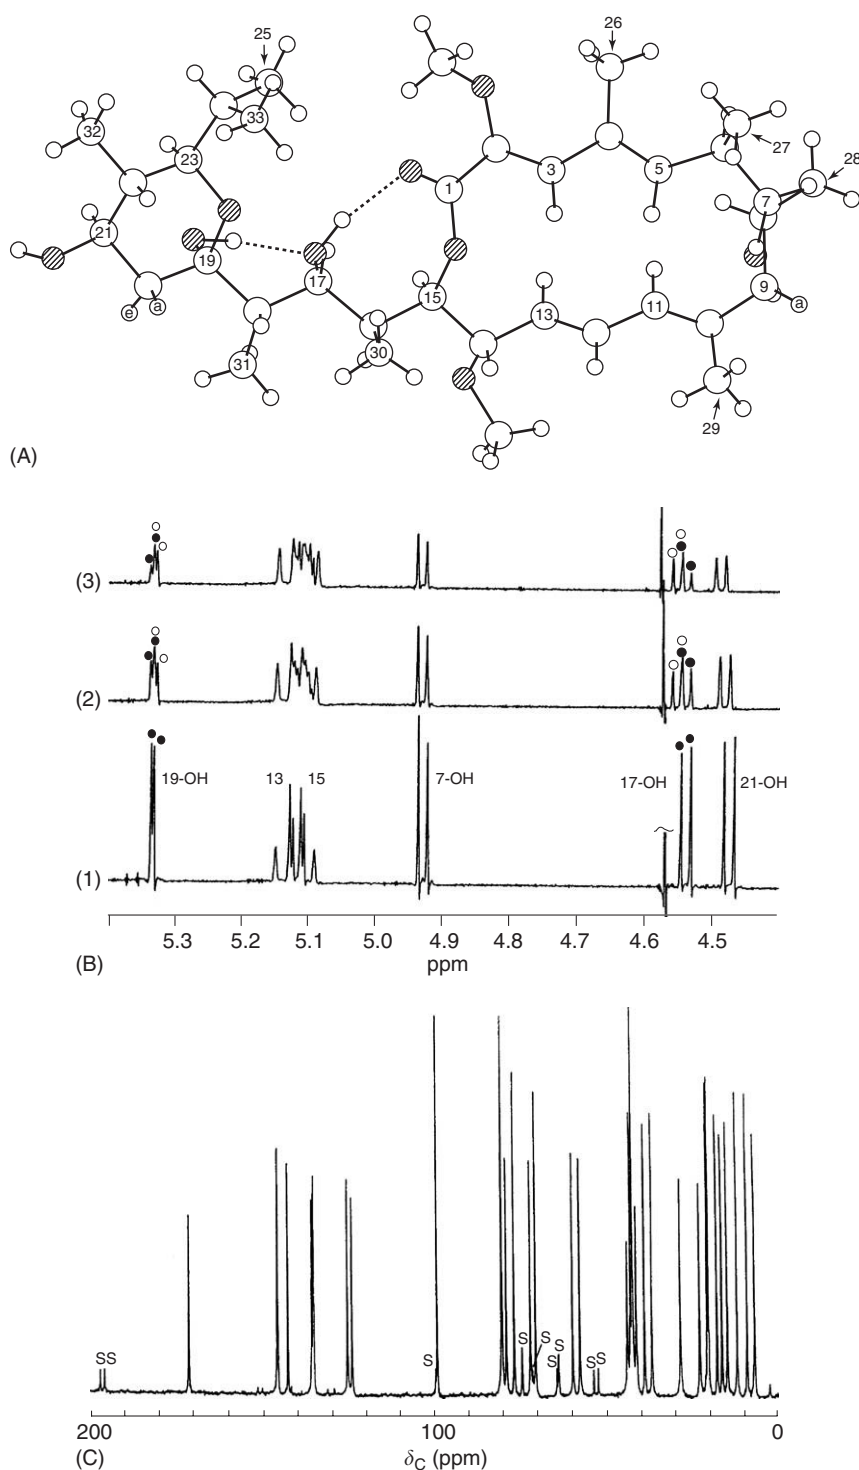

**Figure 5** (A) Crystal structure of erythromycin A hydroiodide dihydrate. The oxygen atoms are shaded; (B) 400 MHz  $^1\text{H}$  NOE difference spectrum obtained by subtraction of a control spectrum from one in which the resonance of H11 was irradiated. The only signals appearing in the NOE difference spectrum are those from protons close in space to H11. (C, D) Expansions of the low-frequency region of the 100 MHz  $^{13}\text{C}$  NMR spectrum of erythromycin A in  $\text{CDCl}_3$ :TMS; (C) Inversion-recovery spectrum with delay  $\tau = 0.25$  s and (D) Normal  $^1\text{H}$  broadband-decoupled spectrum. In an inversion recovery experiment the magnetizations of each  $^{13}\text{C}$  nucleus are inverted with a nonselective  $180^\circ$  pulse and then the relaxation rates of the magnetizations are monitored with a nonselective  $90^\circ$  pulse after a delay  $\tau$ ; the faster the relaxation of the particular nucleus, the more quickly that signal changes from an inverted state back to the relaxed, upright orientation. It is clear that the relaxation rate of methyl-16 is much faster than that of any other methyl group, as predicted for a very hindered environment. The signal for C-14 relaxes rapidly as it arises from a relatively immobile *methylene* carbon. (Reproduced with permission from Everett JR and Tyler JW (1987) The conformational analysis of erythromycin A. *Journal of the Chemical Society, Perkin Transactions II*, 1659–1667; reproduced by permission of The Royal Society of Chemistry.)

solution, as inversion-recovery NMR relaxation experiments show that the relaxation rate of  $\text{CH}_3$ -16 after perturbation is very much faster than that of any other methyl group in the molecule (see Figures 5C and 5D). On the basis of this and much other evidence, it was concluded that the major conformer of erythromycin A in  $\text{CDCl}_3$  solution has a shape very similar to that of the crystal structure.

Hydrogen bonding is often an important determinant of molecular conformation, both in solution and in the solid state. A useful NMR method for probing hydrogen-bonding patterns in solution is SIMPLE NMR, in which  $^1\text{H}$  or  $^{13}\text{C}$  NMR spectra of a compound are taken before and after the addition of a small amount of  $\text{D}_2\text{O}$  to the sample (preferably in a slow-exchanging solvent such as dimethyl sulfoxide). In the case of the hygrolyde antibiotic bafilomycin  $\text{A}_1$  (X-ray structure shown in Figure 6A), the compound was expected to adopt very similar conformations in the solution and crystalline states, on the basis of extensive NMR studies. Figure 6B shows a series of  $^1\text{H}$  NMR spectra of bafilomycin  $\text{A}_1$  both before and after the addition of small amounts of  $\text{D}_2\text{O}$ , resulting in the partial exchange of OH for OD in the hydroxy groups. The resonances of hydroxyl protons involved in a hydrogen-bonding network, such as  $-\text{O}-\text{H} \cdots \text{O}-\text{H}$ , are expected to split into two on the addition of  $\text{D}_2\text{O}$ , as each of the hydroxyl protons experiences a different chemical shift according to whether or not its partner hydroxyl group carries an H or D. The splitting observed for the C19-OH and C17-OH protons confirms the existence of the C19-O-H  $\cdots$  O(17)-H  $\cdots$  O(1)=C (1) hydrogen-bonding network observed in the crystal and inferred in solution from other NMR experiments. The equivalent  $^{13}\text{C}$  SIMPLE experiments are not only useful in studies of hydrogen bonding but are invaluable in structure determination exercises in distinguishing between carbons bearing hydroxyl groups and those bearing substituted oxygen atoms: the former group of carbons will suffer large, low-frequency, two-bond isotope effects (C-OD versus C-OH  $\sim -0.1$  ppm) whereas the latter group will not. Smaller three-bond and longer-range isotope effects are also often observed and are similarly useful in spectral assignment and structure elucidation.

**Solid state** Materials that have the same chemical composition but a different solid-state form are known as polymorphs. Polymorphs can arise if QJ; recrystallizations are carried out under different conditions and they can have different physical properties such as melting point, rate of dissolution, and rate of decomposition. Thus, a clear understanding of polymorphism is crucial to efficient drug

**Figure 6** (A) The crystal structure of the hygrolyde antibiotic bafilomycin A<sub>1</sub>: the two hydrogen bonds between C19–OH, C17–OH, and O1 are shown with dotted lines, carbon atoms 1, 2, 3, 4, 5, 10, 11, 12, and 13 are sp<sup>2</sup> hybridized. (B) A series of 400 MHz SIMPLE <sup>1</sup>H NMR spectra of bafilomycin A<sub>1</sub> in d<sub>6</sub>-dimethylsulfoxide in the region of the hydroxyl proton signals: (1) normal; (2) after the addition of 1.0 μl D<sub>2</sub>O; and (3) after the addition of 2.0 μl D<sub>2</sub>O. The solid and open circles indicate the signals of OH protons hydrogen-bonded to OH and OD partners, respectively; (C) The CPMAS <sup>13</sup>C NMR spectrum of solid, crystalline bafilomycin A<sub>1</sub>. development, as one polymorph of a drug may be much more readily absorbed in the body, or easier to formulate into the final dosage form than another. Solid-state  $^{13}\text{C}$  NMR spectroscopy is a very powerful method of analyzing polymorphism and is widely used in conjunction with FTIR, powder X-ray diffraction, differential scanning calorimetry, and increasingly, single-crystal X-ray crystallography. Different polymorphs, that is, solid-state forms, of the same compound will have different NMR chemical shifts (of the order of a few tenths of ppm) in their solid-state  $^{13}\text{C}$  NMR spectra. The signals in solid-state  $^{13}\text{C}$  NMR spectra are much broader than those in the corresponding solution-state spectra, but this effect is less pronounced for crystalline samples. For instance, the  $^{13}\text{C}$  NMR spectrum of solid, crystalline bafilomycin  $\text{A}_1$  (Figure 6C, see Figure 6A for the structure) exhibits excellent resolution. This cross-polarization magic angle spinning (CPMAS)  $^{13}\text{C}$  NMR spectrum was acquired with magic angle spinning (MAS) at 3600 Hz in order to eliminate broadening due to chemical shift anisotropy, with cross-polarization (CP), i.e., transfer of the magnetization from the protons to the carbon-13 nuclei to improve sensitivity, and with high-power  $^1\text{H}$  decoupling to eliminate dipolar and spin-spin  $^1\text{H}$ ,  $^{13}\text{C}$  couplings.

### Analysis of Purity and of Impurities

NMR spectroscopy can be a useful tool for the quantitative analysis of chemical samples since, given certain provisos, the area of a signal observed in the spectrum is directly proportional to the number of nuclei giving rise to that signal, and in principle no calibrations or extinction coefficients need to be used. The provisos necessary include: (1) complete relaxation of the spin systems of interest; (2) absence of differential NOEs; (3) uniform radiofrequency excitation across the entire spectral width; (4) adequate analog-to-digital converter resolution in situations of high sample dynamic range, i.e., the need to measure very small peaks in the presence of big ones; (5) absence of overlap of the signals of interest; (6) lack of distortion of the data by any processing routines; and (7) adequate correction of any baseline distortions prior to the measurement of signal areas by integration or peak fitting. Given these provisos, it is possible to precisely measure an impurity in a sample down to the level of a few tenths of a mole per cent. However, it is sometimes found that NMR measurements of absolute purity levels of drug substances in relation to a reference standard of known purity are less precise than those obtained by separation methods, which are generally preferred.

A major new advance in this area is the development of online, liquid chromatography (LC)–NMR for both isocratic and gradient elution LC. Using a 600 MHz NMR spectrometer with a purpose-designed probe, it is now possible to obtain stop-flow  $^1\text{H}$  NMR spectra of impurities down to the  $\sim 25$  ng level. LC–NMR offers the prospect of solving the structures of components in mixtures (impurities, natural products, and biofluid components) without further separation. Use of this technology is bound to increase in the future, especially with the advent of integrated LC–NMR–MS systems that allow the integrated acquisition of UV, NMR, and MS data on the same sample.

## Biological Samples

### Molecular Structure Elucidation

**Structural biology – the molecular structure elucidation of biological macromolecules** With the advent of NMR spectrometers operating at 600 MHz and above for protons and using sophisticated 2-D, 3-D, and 4-D NMR experiments, often in conjunction with  $^{15}\text{N}$  and  $^{13}\text{C}$  isotopic labeling, it has been possible for sometime to solve the very complex  $^1\text{H}$  NMR spectra of biomacromolecules such as proteins with molecular masses up to 25 000 Da, and to determine the 3-D structures and dynamics of these molecules in solution. However, many proteins of interest to drug discovery are significantly higher in molecular weight. These large molecules had been intractable to structure elucidation by NMR spectroscopy because of the broad lines that they exhibit in their NMR spectra because of slow tumbling in solution. A new class of Transverse Relaxation Optimized Spectroscopy (TROSY) experiments has helped to break through this molecular weight barrier. TROSY exploits constructive interference between two relaxation mechanisms (chemical shift anisotropy and dipole–dipole coupling) in order to suppress the rapid relaxation that gives rise to the broad lines. However, whilst this has been a significant breakthrough, it is clear that X-ray crystallography remains the preeminent technology for protein (and nucleic acid) structure elucidation, especially in the pharmaceutical industry. The reasons for this preference are many-fold and include: (1) increased success of protein crystallization technologies; (2) lower sample mass requirements than NMR; (3) ability to determine structure from ever smaller crystals due to increased X-ray beam flux and new detector technologies; (4) faster structure solution, especially for complexes of drugs with a known protein; and (5) more precise structures due

to the innate advantage of having molecular structural constraints over large distances. There is no question that NMR spectroscopy retains the advantage of solving the protein structures in the solution state and providing information on molecular dynamics, but at the time of writing nearly all pharmaceutical industry structural biology is exploited using X-ray crystallography. This position could change if new NMR technologies appear that allow faster structure solution on small samples, especially if NMR could tackle the current Achilles heel of X-ray: its inability to solve membrane protein structures easily because of reagent provision and crystallization difficulties. Because of the issues mentioned above, many NMR spectroscopists working with proteins in pharmaceutical R&D have turned their skills and the technology to a new application; hit- and lead-finding.

### Hit- and Lead-Finding Using NMR Technologies

The traditional pharmaceutical drug discovery paradigm involves the following steps:

1. Selection of a protein (usually) target on the basis of its linkage to a disease of importance and its amenability to intervention with (usually) small molecule therapeutics.
2. Generation of the protein reagent and design and development of a robust assay for the reagent that can be used in high-throughput screening (HTS) mode.
3. Execution of the HTS against a screening file that could comprise hundreds of thousand or even millions of compounds in order to generate 'hits' against that target that can then be optimized into leads and eventually drug candidates in development.

Recently, there has been a surge of interest in the application of various NMR technologies that provide an alternative hit-finding technology. The technologies rely on detecting ligand-macromolecule binding through observations of changes in the NMR spectra of either the ligand or the macromolecular target (see the reviews by Pellechia *et al.* and by Stockman and Dalvit). One of the first methods was the 'SAR by NMR' method developed by Stephen Fesik and co-workers at Abbott laboratories (Figure 7). In this method, low-molecular-weight drug fragments are screened against a  $^{15}\text{N}$ -labeled protein. Drug fragments that cause changes to the  $^{15}\text{N}$  or  $^1\text{H}$  chemical shifts of the amide groups in the  $^{15}\text{N}$  HSQC NMR spectra of the protein molecule are judged to be binding; the region of binding can be determined if the spectral data have been assigned. Iterative

**Figure 7** In SAR by NMR, amide NH chemical shift changes in a protein are used to infer binding of a ligand to a particular region. This figure represents the process (as a cartoon) for constructing a potent bidentate compound for a protein target (blue) with two adjacent binding sites I and II. (A) native protein, both binding sites empty; (B) small molecule ligand (green) is found that binds to binding site II by monitoring chemical shift mapping; (C) further screening leads to the discovery of another ligand (green) with optimized binding, i.e., optimized fit to binding site II; (D) and (E) the process is repeated for binding site I (red ligands); the two optimized ligands are then joined by a linker (black); this can rapidly lead to nanomolar binding affinity bidentate compounds, based on tethering two micromolar ligands together.

screening with related fragments can then optimize the binding of the ligand. In SAR by NMR the process is then repeated to discover an optimized binding fragment for a second, adjacent binding site. The locations of the two binding fragments in the protein structure are then determined by NMR or X-ray crystallography, and a linker is designed to join them together, often resulting in a more potent hit molecule. Many variations on this theme have been developed, including methods that monitor the

effects of binding upon ligand NMR relaxation times or diffusion properties. The advantages of these various NMR methods relative to conventional HTS technologies include:

- no need to know the natural ligand for the protein target;
- no need to know the function of the target;
- can find weak binding hits that may be interesting to optimize and may be missed by conventional methods;
- no requirement for extensive assay development and validation; and
- capable of finding hits against allosteric binding sites.

### NMR Spectroscopy of Biological Fluids: Metabonomics

NMR spectroscopy of biofluids, especially of urine, serum, and plasma, is being increasingly used in the pharmaceutical industry in studies of drug metabolism, drug safety, and clinical efficacy. The great advantage of NMR in this area is that it is a non-selective detector and will report on the levels of all low molecular mass biofluid components above the detection threshold of the particular experiment (generally better than 100 nmol for  $^1\text{H}$  NMR at 600 MHz). By contrast, many chromatographic techniques require preselection of conditions (column, eluent, etc.), which can result in the selective detection of only certain components within a complex sample such as a biofluid. This nonselective detector attribute has resulted in biofluid NMR analyses discovering previously unknown drug metabolites and biomarkers for toxic lesions and disease states.

**Metabonomics** The study of genomics and proteomics has become well established over the past decade. A new complementary science, metabonomics, has also emerged recently, which is less familiar but will become increasingly important in the future for pharmaceutical R&D. Metabonomics is defined as ‘The quantitative measurement of the multiparametric metabolic response of living systems to pathophysiological stimuli or genetic modification’. Thus, metabonomics is an *in vivo* or systems biology approach to the study of the metabolite pools (metabonomes) in living systems and how those pools reflect health and disease, aging, drug treatment, and environmental influences. Metabonomics has many application areas including:

- response of an organism to the administration of a toxin; and
- development and application of metabolic biomarkers for drug safety and efficacy.

NMR plays a key role in metabonomics as the science is typically studied by measuring the metabolite pools in various biofluids or tissues using NMR spectroscopy, although other technologies such as MS or LC–MS can be employed.

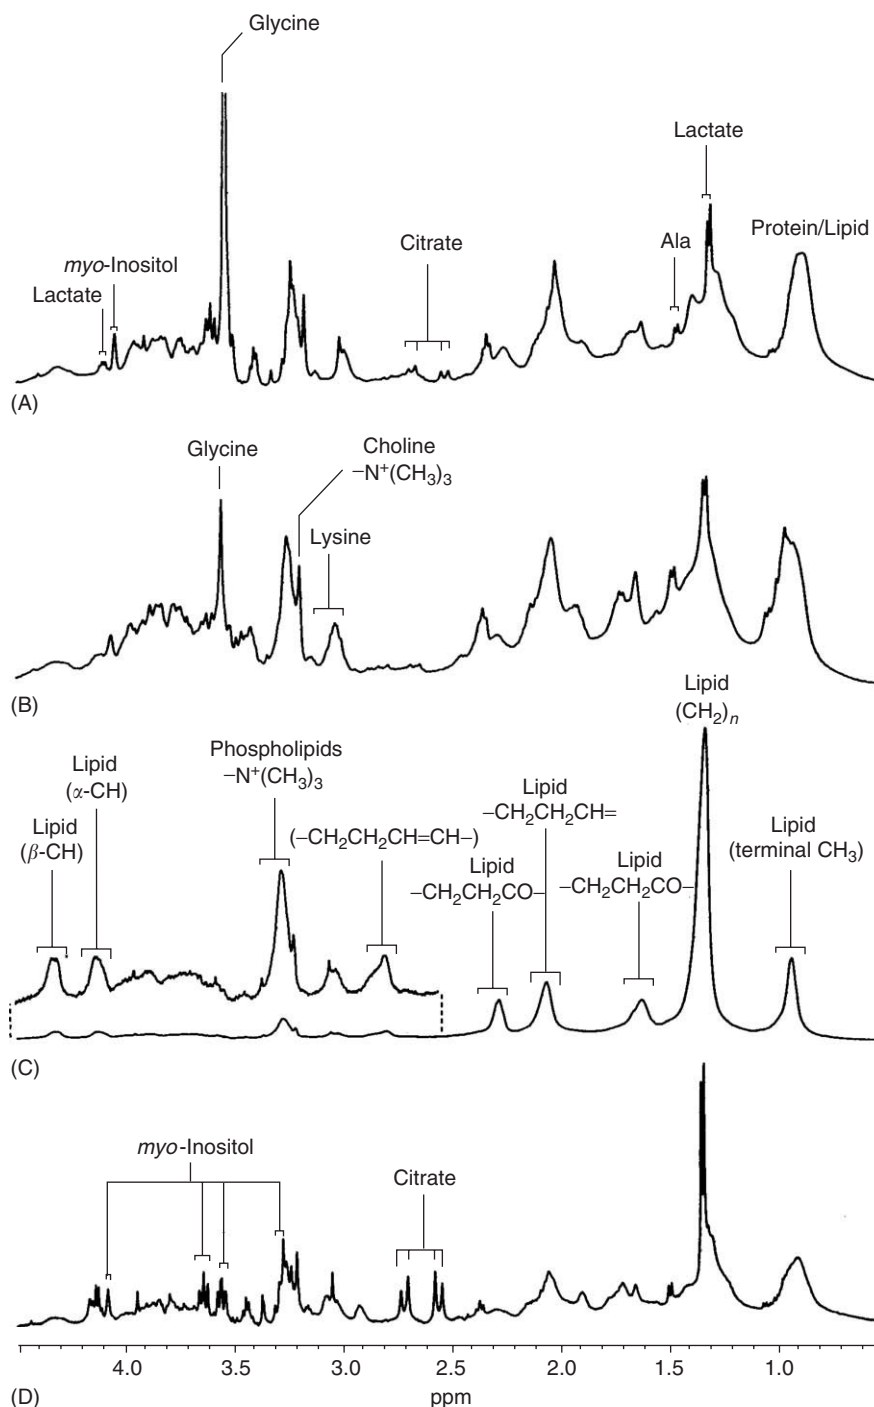

Figure 8 shows expansions from magic angle spinning  $^1\text{H}$  NMR spectrum of human prostate tissue samples. Differences were observed between the spectra of intact prostate tissue from benign prostatic hyperplasia and cancer patients. This example demonstrates that NMR methods can be applied to semisolid tissues as well as to biofluids, and points to the useful information that NMR can provide in these disease states.

In contrast to the tissue spectra, which have relatively broad signals, the 900 MHz  $^1\text{H}$  NMR spectrum of human urine exhibits thousands of (mostly) sharp lines due to the signals of hundreds of endogenous metabolites. Except in cases of dramatic or simple changes, it can be very difficult to interpret changes in such a complex spectrum and therefore computer-aided pattern recognition (PR) technologies have come to the fore to aid spectral analysis. PR methods may be unsupervised; that is, the algorithm is not informed about the group to which the subject belongs, e.g., treated versus controls, or they may be supervised, where the algorithm is informed about group membership. In each case, the purpose of the analysis is to achieve complexity reduction and reduce the dimensionality of the analysis problem. Each NMR spectrum can be thought of as a multidimensional object in chemical shift space. Indeed, most PR methods split each spectrum into  $\sim 200$  ‘buckets’ or windows, each  $\sim 0.04$  ppm wide. The spectrum is thus a 200 dimensional object with an intensity value for each dimension. In one popular unsupervised method, principal components analysis, the complex high-dimensional space is reduced to two or three dimensions, so that clustering of samples of the same type, or significant changes to the spectra, can be easily visualized.

### NMR Spectroscopy and Imaging of Living Systems

This area covers a wide range of applications from studies of biosynthesis, metabolism, and toxicity in living cells, to studies of metabolism in perfused whole organs and tissues, right through to imaging and metabolism studies of human beings and animals.

- response of an organism to disease and the treatment of that disease with medicines;

**Figure 8** 500 MHz  $^1\text{H}$  NMR magic angle spinning spectra of prostatic tissue from humans with malignant prostate cancer sampled by transurethral radical prostatectomy (TURP) (A), or needle biopsies (B, C) contrasted with that of a benign prostatic hyperplasia (BPH) patient sampled via radical prostatectomy (D). Spectrum (C) is different, as the needle has sampled a different region of the prostate. The spectrum of the prostate tissue from the BPH patient (D) displays higher levels of citrate but lower lipid levels relative to spectra (A) and (C) from the malignant cancer patients. (See Tomlins AM, Foxall PJD, Lindon JC, Lynch MJ, Spraul M, Everett JR, and Nicholson JK (1998). *Analytical Communications* 35: 113–115).

NMR studies of isolated organs have been widely used to investigate metabolic processes *in vivo* and their responses to various experimental interventions. In particular, the perfused isolated heart has

been extensively studied by  $^{31}\text{P}$  NMR spectroscopy as an aid to the understanding of the action of cardiovascular drugs.  $^{31}\text{P}$  spectra of the intact beating heart exhibit distinct resonances for ATP,

phosphocreatinine, inorganic phosphate, and phosphoesters, some of which play key roles in energy metabolism. The technology is well suited to the study of the efficacy of, for instance, cardio-protective agents in mitigating the effects of ischemia on the heart tissue. However, we will now focus on NMR applications to whole animals and human beings.

One major goal of modern medical research is to develop noninvasive methods of diagnosing diseases and monitoring their responses to therapy. Magnetic resonance imaging (MRI) and the complementary technique of magnetic resonance spectroscopy (MRS, i.e., NMR spectroscopy on living humans and animals) have themselves developed to such an extent that they are now used routinely in this role, both in the clinic and to a lesser extent in pharmaceutical research and development. In pharmaceutical research it is still necessary, or obligatory, to test experimental drugs on small laboratory animals, especially rodents, to establish both efficacy and safety, prior to their first administration to humans. The application of MRI and MRS to the study of disease models in rodents presents great technical problems relative to the clinical situation, because the small size of the animal results in poorer sensitivity and/or resolution. However, there are great benefits to be gained from the use of noninvasive imaging procedures to monitor diseases and drug therapy in experimental animals, because the same animals can be followed over long time periods, reducing the numbers of animals that need to be used. The biological significance of the results obtained is also improved relative to those obtained with invasive methods, since each animal can serve as its own control.

There are many areas of application of MRI and MRS in pharmaceutical research, including arthritis, cancer, cardiovascular diseases, central nervous system diseases, renal diseases, respiratory tract diseases, and various toxicological applications. In general, MRI is better established than MRS, although very rapid progress is being made in the latter area. For instance, it is now possible to obtain spatially localized  $^1\text{H}$  or  $^{31}\text{P}$  NMR spectra on small volumes of interest within animals or human beings.

**Magnetic resonance imaging** Arthritis is the largest single cause of disability in the UK. Rheumatoid arthritis (RA) is a severe form of the disease that is characterized by a primary inflammation in the joints, followed by later erosion and remodeling of the bones: no effective treatments exist for RA. Whilst X-radiography is well suited to monitoring changes in the bones, detection of the earlier,

soft-tissue phase of RA is difficult. MRI has emerged as an excellent tool with which to monitor the early inflammatory and later erosive stages of arthritis in both animals and man. This is well illustrated in Figure 9, which shows two  $^1\text{H}$  MR images of the knee joints of a rat with arthritis. The image of the normal knee (Figure 9A) clearly visualizes both the bony and soft tissues, including the cortical

**Figure 9**  $^1\text{H}$  magnetic resonance images in a sagittal plane through the knee of a rat with arthritis: (A) normal, (B) at day 12 of arthritis. See the text for an explanation of the labeling. (Reproduced with permission from Carpenter TA, Everett JR, Hall LD, *et al.* (1994) *Skeletal Radiology* 23: 429–437; © Springer-Verlag.)

bone (CB), the calcified menisci (M), and the patellar ligament (LP) (dark regions), the synovial fluid and epiphyseal cartilage (bright), and the articular cartilage (AC), bone marrow (BM), and deep muscle (intermediate intensity). By contrast, the image of the rat at a later stage of arthritis shows the presence of the inflammatory pannus (P), erosion of the bone outline (E), and both high-intensity region (HR) and low-intensity region (LR) within the bone, which are associated with erosion and remodeling, respectively. This methodology allows the time course of the disease and its response to drug treatments to be monitored over long periods of time in a single group of animals, thus reducing the use of experimental animals, decreasing biological variability, and expediting the evaluation of novel anti-arthritic agents.

## Emerging Techniques

In 10 years time, the face of pharmaceutical NMR is likely to have changed in a number of significant ways. Metabonomics is emerging as a technology of central importance to pharmaceutical R&D as the industry struggles with the twin imperatives of increasing the confidence in safety of the drugs in its R&D portfolio and the confidence in the biological rationale of the targets that its drugs are directed against; metabonomics will impact upon both these imperatives. The power of computing systems will drive ever more sophisticated and more automated NMR data analysis for molecular structure elucidation and for biological sample analysis. A totally new approach to multidimensional NMR has just emerged, which promises to reduce by orders of magnitude the data acquisition times for the demanding 3D, 4D, and higher-dimensional NMR experiments required for protein structure elucidation. GFT NMR (G-matrix and Fourier transform NMR) is predicted to revolutionize the use of NMR in structural biology. NMR methods are also likely to play a more important role in kick-starting the drug discovery process by providing alternative hit-finding methods to conventional HTS. An exciting era lies ahead of us.

## Proton NMR in Biological Objects Subjected to Magic Angle Spinning

R A Wind and J Z Hu, Pacific Northwest National Laboratory, Richland, WA, USA

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

Magnetic resonance imaging (MRI) of the spatial distribution of water in biological objects has developed as one of the major tools to diagnose lesions and diseases and follow the therapy response in animals and patients in a minimally invasive way. In addition, *in vitro* and *in vivo* localized magnetic resonance spectroscopy (MRS) and spectroscopic imaging or chemical shift imaging (CSI) are increasingly used in biochemical and biomedical studies in cells, tissues, animals, and humans. With these techniques the resonance lines of several relatively small molecular weight chemical compounds such as amino acids, lipids, and other key mobile metabolites are measured, and their presence and intensities have been linked to tumor phenotype, tumor formation, tumor size, increased cell proliferation, and cell death pathways. However, a major problem associated with nuclear magnetic resonance (NMR) spectroscopy in intact biological tissues is that relatively large resonance line widths are observed, often one to two orders of magnitude larger than the widths measured in liquids using established NMR techniques. This is especially a problem for  $^1\text{H}$  NMR, which is the most widely used nucleus because of its relatively large NMR sensitivity, but has a relatively small chemical shift range of  $\sim 10$  parts per million (ppm). As usually many metabolites contribute to the NMR signal, the result is a spectrum with severely overlapping spectral lines, which seriously hampers a quantitative analysis of the spectra, and sometimes even makes it impossible to assign the spectral lines unambiguously.

In biological samples, the main mechanisms for this broadening are the local magnetic field gradients arising from variations in the isotropic bulk magnetic susceptibility near boundaries of intra- and extracellular structures, such as the various intracellular compartments, air-tissue interfaces near the lungs and sinuses, and bone-tissue interfaces. Then, chemically equivalent nuclei experience different local magnetic fields, depending on their spatial localization, giving rise to line broadening. Using cell extracts can eliminate this broadening, but this

procedure is time consuming, introduces spectral artifacts, and cannot be applied to study intact tissues and organs. Another method of improving the spectral resolution is to increase the external magnetic field  $B_0$ , as the separation between the lines in an NMR spectrum increases linearly proportional with  $B_0$ . However, the susceptibility-induced broadening is linearly proportional to  $B_0$  as well, and in many cases zero or only marginal improvements in the spectral resolution have been reported when higher field strengths were employed.

In principle, the susceptibility broadening can be averaged to zero by the technique of magic angle spinning (MAS), where the sample is rotated about an axis making an angle of  $54^\circ 44'$  relative to the external magnetic field. In a standard MAS experiment, where the NMR signal is observed after a single  $90^\circ$  radio frequency (RF) pulse (to be called single-pulse MAS or SP-MAS hereafter), the spinning frequency must be larger than the broadening in order to avoid the occurrence of spectral spinning sidebands (SSBs) surrounding the various resonance peaks, which can overlap with other resonance lines, rendering the interpretation of the spectra difficult again. In fact, in practice often the spinning frequency is chosen larger than the spectral width, i.e., a kilohertz or more, in order to avoid SSBs arising from the water signal, which occurs in biological objects in a concentration of  $\sim 30 \text{ mol l}^{-1}$ , and which is often much stronger than the metabolite signals, arising from compounds with two to three orders of magnitude smaller concentrations, even when water suppression is applied. **Figure 1** shows  $^1\text{H}$  water-suppressed NMR metabolite spectra of excised rat liver, obtained in a 7T external field (i.e., 300 MHz proton frequency) on a stationary sample and with SP-MAS at different spinning speeds, illustrating the appearance of SSBs at low spinning speeds. In fact, at 1 Hz spinning the side bands are so dense that the spectrum is virtually the same as the static spectrum. In these experiments, water suppression was achieved by preceding the  $90^\circ$  pulse by a DANTE (delays alternating with nutations for tailored excitation) water suppression sequence, consisting of a train of equally spaced small-tip-angle hard pulses.

A serious problem associated with fast SP-MAS is the large centrifugal force,  $F_c$ , induced in the sample by the spinning, which destroys tissue structures and even individual cells at high spinning rates.  $F_c$  is

**Figure 1** 300 MHz  $^1\text{H}$  NMR spectra of freshly excised rat liver samples obtained with different methods: (A) static sample; (B) 1 Hz SP-MAS; (C) 40 Hz SP-MAS; (D) 4 kHz SP-MAS. The external field was 7 T. Line assignments: 1 ( $\sim 0.88$  ppm), triglycerides  $\text{CH}_3$  terminal, or neutral amino acid methyl, valine, leucine, isoleucine methyl; 2 ( $\sim 1.28$  ppm), triglycerides  $-(\text{CH}_2)_n$ , lactate methyl, threonine methyl; 3 ( $\sim 2.04$  ppm), triglycerides  $\text{CH}=\text{CH}-\text{CH}_2-\text{CH}_2$ ; 4 ( $\sim 2.24$  ppm), triglycerides  $\text{CH}_2-\text{CH}_2-\text{CO}$ ; 5 ( $\sim 2.8$  ppm), triglycerides  $\text{CH}=\text{CH}-\text{CH}_2-\text{CH}=\text{CH}$ ; 6 ( $\sim 3.2$  ppm), choline methyl, phosphocholine methyl,  $\beta$ -glucose, trimethylamine-*N*-oxide methyl; 7 (3.4 ppm), 8 (3.6 ppm), glucose, glycogen; and 9 (3.8–4.0 ppm), glucose, glycogen, amino acids. (Reproduced with permission from Wind RA and Hu JZ (2003) Magnetic susceptibility effects in nuclear magnetic resonance spectroscopy of biological objects. In: *Recent Research Developments in Magnetism and Magnetic Materials*, vol. 1, pp. 147–169.)

given by  $F_c = m\omega^2 r$ , where  $m$  is the mass,  $\omega = 2\pi F$ ,  $F$  being the spinning frequency, and  $r$  the distance from the rotation axis to the point of interest. For example, when  $F = 2$  kHz and  $r = 1$  cm,  $F_c = 1.6 \times 10^5$  times the gravitational force  $F_g$ . Therefore, the SP-MAS method is not viable for MRS or CSI in large intact biological samples or *in vivo* studies, and methods are needed that yield high-resolution, SSB-free spectra at reduced MAS frequencies. In the remainder of this article, two such methods and some applications will be discussed, following short background introductions about magnetic susceptibility and MAS.

## Magnetic Susceptibility

The magnetic susceptibility factor  $\chi$  arises from the magnetization  $\mathbf{M}$  induced in a material exposed to an external magnetic field  $\mathbf{H}_0$ , corresponding to a magnetic induction  $\mathbf{B}_0 = \mu_0 \mathbf{H}_0$ , in the absence of the material, where  $\mu_0 = 4\pi \times 10^{-7}$  (T m A $^{-1}$ ) is the magnetic permeability in vacuum. When the magnetization is oriented in the same direction as  $\mathbf{B}_0$ ,  $\chi$  is a scalar and the susceptibility is called isotropic.  $\chi$  is called the volumetric susceptibility and is a unitless quantity defined as  $\chi = \mathbf{M}/\mathbf{H}$ , where  $\mathbf{M}$  is the magnetic dipole moment per unit volume and  $\mathbf{H}$  is the total magnetic field strength.  $\chi$  is equal to 0 in free space and is practically 0 for air. In biological systems, the

additional magnetic field strength induced by  $\mathbf{M}$  is much less than  $\mathbf{H}_0$  so that  $\chi \approx \mathbf{M}/\mathbf{H}_0$ . With this definition, in the material the net magnetic field induction  $\mathbf{B}$ , which is the fundamental magnetic field responsible for NMR, is given by  $\mathbf{B} = \mu_0 \mathbf{H}_0 + \mu_0 \mathbf{M} \approx (1 + \chi)\mathbf{B}_0 = \mu_r \mathbf{B}_0$ , where  $\mu_r$  is the relative magnetic permeability.  $\mathbf{M}$  can arise from several sources: (1) The nuclear magnetization. Although this magnetization is responsible for the MR signal, its contribution to  $\mathbf{M}$  can usually be neglected. (2) The magnetization associated with slight changes in the angular velocities of paired electrons in their orbitals, induced by  $\mathbf{B}_0$ . According to Lenz's law this will cause a magnetic field at the center of the orbital that opposes  $\mathbf{B}_0$ , resulting in the well-known chemical shift. Outside the orbital at a distance large compared with the dimensions of the orbital, the effect of  $\mathbf{B}_0$  on an electron orbital can be approximated by a local magnetic field arising from a magnetic dipole associated with a ring current in the orbital. This results in a negative value of  $\chi$ , the diamagnetism. (3) Paramagnetic susceptibility arises in materials containing unpaired electrons, resulting in a positive value of  $\chi$ . (4) Ferromagnetism occurs in materials possessing permanent magnetic moments aligned in Weiss domains.

Most biological objects are diamagnetic. Water and organic compounds possess susceptibility factors  $\chi$  of the order of  $-4\pi \times 10^{-6}$ . In liquids, this

susceptibility gives rise to an induced additional homogeneous magnetic field in the sample, resulting in a shift of the resonance lines rather than a line broadening. However, in biological samples, which contain many intra- and intercellular structures, the various compounds are distributed heterogeneously, and often close to a boundary of a material with a different susceptibility factor. Then, the susceptibility differences between the various compartments induce magnetic field gradients in the sample. As a result the resonance shifts become space dependent, resulting in a line broadening. Often, line widths of the order of 0.5 ppm are observed, at least one order of magnitude larger than their intrinsic line widths. These values are in accordance with estimations based on the susceptibility differences one can encounter at interfaces in biological objects.

## Magic Angle Spinning

In order to illustrate the effect of MAS we consider the magnetic moment  $\mathbf{m}$  arising from a sphere of a stationary diamagnetic material (see Figure 2A). At a distance  $R$  equal to or larger than the radius  $a$ , the magnetic field generated by this moment has two components  $B_r$  and  $B_\gamma$ , oriented in the direction and perpendicular to  $R$ , respectively. These components are given by

$$B_r = \frac{\mu_0}{2\pi} \frac{m \cos \gamma}{R^3} \quad \text{and} \quad B_\gamma = -\frac{\mu_0}{4\pi} \frac{m \sin \gamma}{R^3}$$

where  $\gamma$  is the angle between  $R$  and the direction of the magnetic moment, defined as the  $z$  direction. It follows that the dipolar field component along the  $z$ -axis,  $B_z$ , is given by

$$B_z = B_{rz} + B_{\gamma z} = \frac{\mu_0 m}{4\pi R^3} (3 \cos^2 \gamma - 1) \quad [1]$$

Figure 2B shows the case that the sample is rotated with an angular frequency  $\omega_r$  about an axis making an angle  $\beta$  with the external field. Then, the angle  $\gamma$  and the azimuth angle  $\phi$  become time dependent, and  $\cos \gamma(t)$  is given by

$$\begin{aligned} \cos \gamma(t) &= \cos \alpha \cos \beta + \sin \alpha \sin \beta \cos[\phi(t)] \\ &= \cos \alpha \cos \beta + \sin \alpha \sin \beta \cos(\omega_r t + \phi_0) \end{aligned} \quad [2]$$

$\alpha$  is the angle between the rotation axis and  $R$ . Equation [1] becomes

$$\begin{aligned} B_z &= \frac{\mu_0 m}{8\pi R^3} \{ (3 \cos^2 \alpha - 1)(3 \cos^2 \beta - 1) \\ &\quad + 3 \sin 2\alpha \sin 2\beta \cos(\omega_r t + \phi_0) \\ &\quad + 3 \sin^2 \alpha \sin^2 \beta \cos[2(\omega_r t + \phi_0)] \} \end{aligned} \quad [3]$$

Hence,  $B_z$  contains a static term and two time-dependent terms. Then, in a standard SP-MAS experiment after Fourier transformation the NMR spectrum arising from the interactions between the nuclear spins and these local fields consists of a center-band line, located at the frequency determined by the static term, and SSBs, located at frequency

**Figure 2** Magnetic dipole field outside a sphere of a diamagnetic material with dipolar moment  $\mathbf{m}$  induced by the external field  $\mathbf{B}_0$ : (A) static sample; (B) rotating sample. In: *Recent Research Developments in Magnetism and Magnetic Materials*, vol. 1, pp. 147–169.)

distances  $\pm n\omega_r$ ,  $n = 1, 2, 3, \dots$ , from the center-band line and with amplitudes depending on the static line width and  $\omega_r$ . Hence, by choosing the angle  $\beta = \cos^{-1}\sqrt{3} = 54.74^\circ$ , the effect of the static term becomes zero, irrespective of the angle  $\alpha$ , and for spinning speeds much larger than the spectral line widths the SSBs have very small amplitudes and can often be neglected. As a result, the susceptibility shift in a homogeneous liquid and the susceptibility line broadening in heterogeneous samples are eliminated. Moreover, MAS eliminates other line broadenings as well, arising from other interactions with a similar angular dependence as eqn [1]. Table 1 summarizes the various interactions that can occur in a material and the effectiveness of MAS in averaging out these interactions. As already mentioned above,

**Table 1** The impact of magic angle spinning on the various spin interactions playing a role in NMR

Interaction	Impact of MAS <sup>a</sup>
Indirect spin–spin or <i>J</i> -coupling	N
Static spin–spin dipolar coupling	Y
Isotropic chemical shift	N
Static anisotropic chemical shift	Y
First-order quadrupolar coupling	Y
Second-order quadrupolar coupling	P
Isotropic susceptibility	Y
Anisotropic susceptibility	P
Spin–lattice relaxation time $T_1^b$	N
Intrinsic spin–spin relaxation time $T_2^b$	N

<sup>a</sup>Y: MAS averages the interaction to zero, N: MAS does not affect the interaction, P: MAS partially averages the interaction.

<sup>b</sup>If determined by interactions rendered time-dependent by molecular motions.

in biological materials the (dia)magnetic susceptibility is the main source of the line broadening observed in stationary samples.

## Slow-MAS Techniques

In solid-state NMR, several methods have been developed where slow MAS is combined with special RF pulse sequences to suppress the spinning sidebands or to separate them from the isotropic spectrum so that a sideband-free high-resolution isotropic spectrum is obtained. Examples of such methodologies are total suppression of spinning sidebands (TOSS), phase-adjusted spinning sidebands (PASS), and phase-corrected magic angle turning (PHORMAT). While TOSS cannot be used at low spinning speeds because of serious spectral distortions, it was found that PASS and PHORMAT can be modified successfully for studies of biological samples at low speeds, an order of magnitude or more lower than the speeds typically used in solid-state NMR experiments. The basic RF pulse sequences used in SP-MAS, PASS, and PHORMAT are shown in Figure 3. In the following paragraphs PASS and PHORMAT will be described briefly (SP-MAS is self-explanatory).

### PASS

PASS is a one-rotor-period ( $T_r$ ), constant evolution time 2D experiment, during which five  $\pi$  pulses are applied, with time intervals  $tm_1$ – $tm_6$  (Figure 3B). In PASS, the center-band spectrum and the SSB spectra are separated by order. This is achieved by acquiring

**Figure 3** Three RF pulse sequences used in combination with MAS. The  $90^\circ$  pulses are black while the  $180^\circ$  pulses are gray: (A) SP-MAS; (B) PASS; (C) the prototype PHORMAT. The various timing parameters are explained in the text. (Reprinted with permission from Hu JZ and Wind RA (2002) The evaluation of different MAS techniques at low spinning rates in aqueous samples and in the presence of magnetic susceptibility gradients. *Journal of Magnetic Resonance* 159: 92–100; © Elsevier)

the signal after a series of PASS experiments with different values of the time intervals  $tm_1$ – $tm_6$ . Each combination of time intervals has been chosen in such a way that the contribution of the signal in the observed free induction decay (FID) in the acquisition dimension ( $t_2$ ), arising from the center band and SSBs, is proportional to a phase factor given by  $\exp(-ik\Theta)$ , where  $k$  denotes the sideband order and  $\theta$  is a variable called ‘pitch’. Then after 2D Fourier transform with respect to  $t_2$  and  $\theta$  a series of spectra is obtained that separates the contributions for each  $k$  value, i.e., it separates the center-band and sideband spectra. In practice, it suffices to use  $n$  discrete values of  $\theta$ , varying from 0 and  $2\pi$  in steps of  $2\pi/n$ , where  $n$  denotes the total number of center-band and sideband spectra that have to be resolved. **Figure 4A** shows the stacked  $^1\text{H}$  PASS water-suppressed spectra obtained on excised rat liver in a 7 T field using a spinning speed of 40 Hz. Water suppression was achieved by preceding the PASS sequence by a DANTE sequence. In this PASS experiment, 16 different combinations of delay times  $tm_1$ – $tm_6$  are used, which makes it possible to separate the center-band and 15 sideband spectra without spectral aliasing. **Figure 4B** shows the center-band spectrum separately. It follows that the spectral resolution is at least the same as that obtained in the standard fast SP-MAS experiment shown in **Figure 1D**, and similar results have been obtained in other excised tissues and organs.

## PHORMAT

PHORMAT is a regular 2D experiment, with a variable evolution time and a (fixed) acquisition time (**Figure 3C**). The PHORMAT methodology is based on the so-called magic angle hopping (MAH) experiment, where the sample is hopped over angles of  $120^\circ$  about an axis at the magic angle. In PHORMAT, the sample is spun slowly and continuously instead of hopped. The prototype PHORMAT sequence is shown in **Figure 3C**. The parameter  $T_r$  denotes the rotation period of the sample,  $t_1$  is the variable evolution time, and  $t_2$  is the acquisition time. The  $90^\circ$  pulses labeled  $r_1$ ,  $r_2$ ,  $r_3$ , and  $r_4$  are synchronized to  $1/3$  of the rotor period, and rotate the magnetization into the transverse plane. Then during the evolution periods,  $t_1/3$ , the magnetization precesses through angles  $\Phi_1$ ,  $\Phi_2$ , and  $\Phi_3$ , respectively. The  $90^\circ$  pulses labeled  $p_1$ ,  $p_2$ , and  $p_3$  are the storage pulses, which project a component of the precessing magnetization after the corresponding  $t_1/3$  period to the  $z$ -axis, where it remains during the storage periods labeled L. A FID is acquired following the last  $90^\circ$  pulse ( $r_4$ ). For local fields arising from second-rank interactions, such as interactions with the

magnetic susceptibility fields, the sum of the precession angles  $\Phi_1$ ,  $\Phi_2$ , and  $\Phi_3$  averages to the isotropic values of the interactions, i.e.,  $\Phi_1 + \Phi_2 + \Phi_3 = \omega_{\text{iso}}t_1$ . With a proper phase cycling of the projection pulses,  $p_1$ ,  $p_2$ ,  $p_3$  and the receiver, the FID can be expressed as

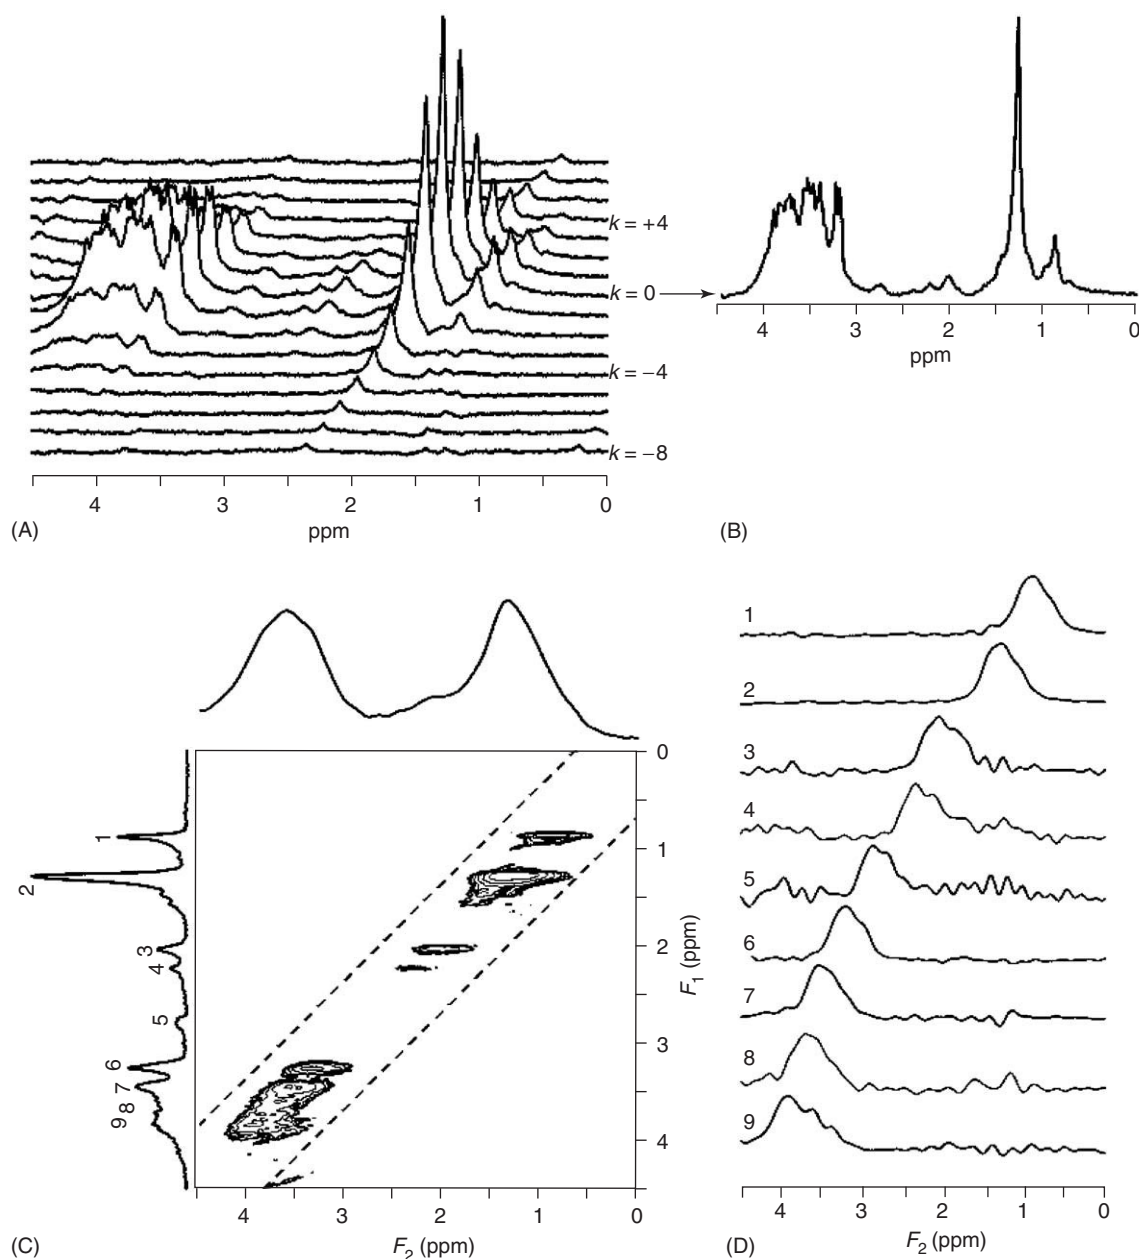

$$\text{FID}(t_2, t_1) = \exp(-i\omega_{\text{iso}}t_1)\text{FID}(t_2) \quad [4]$$

After Fourier transformation as a function of  $t_2$  and then as a function of  $t_1$  a pure absorption-mode 2D spectrum is obtained. **Figure 4C** shows an example of water-suppressed  $^1\text{H}$  PHORMAT metabolite spectra of excised rat liver tissue, obtained at a MAS spinning frequency of 1 Hz and in a 7 T field. **Figure 4C** displays the 2D plot together with the projections along the isotropic  $F_1$  ( $t_1$ ) and anisotropic  $F_2$  ( $t_2$ ) dimensions. By making slices parallel to the  $F_2$  axis, the anisotropic line shapes of each isotropic peak can be determined separately, nine of which are plotted in **Figure 4D**. In this way the susceptibility gradients surrounding individual metabolites can be determined, which could be of diagnostic value. The spectral line widths in the isotropic projection are comparable to, albeit slightly larger than, the widths obtained with 4 kHz SP-MAS (**Figure 1D**) and 40 Hz PASS (**Figure 4B**). As will be discussed in the next section, this slight increase (a few hertz) is attributed to the diffusion of the metabolites in the susceptibility gradients.

## Limitations of SP-MAS, PASS, and PHORMAT

The question arises to what values the MAS frequency can be reduced with the various MAS methodologies, as this will determine the size and type of biological object that can be studied with these techniques. The answer depends on the MAS methodology used and the NMR properties of the magnetic nuclei under investigation. Moreover, the NMR sensitivity per unit measuring time and the total measuring time itself are different for the various techniques. **Figure 5** shows 300 MHz  $^1\text{H}$  SP-MAS, PASS center-band, and PHORMAT isotropic spectra of a mixture of water and spherical glass beads with diameters of  $\sim 230 \mu\text{m}$  as a function of the spinning frequency  $F$ . The susceptibility difference between the beads and water, broadened the static water line to 3.7 kHz (12.5 ppm), at least a factor 20 larger than the line widths observed in biological systems. For SP-MAS it follows that  $F$  has to be at least of the order of the static line width in order to reduce the SSBs. In contrast, it follows from **Figure 5** that PASS produces a nearly sideband-free isotropic chemical

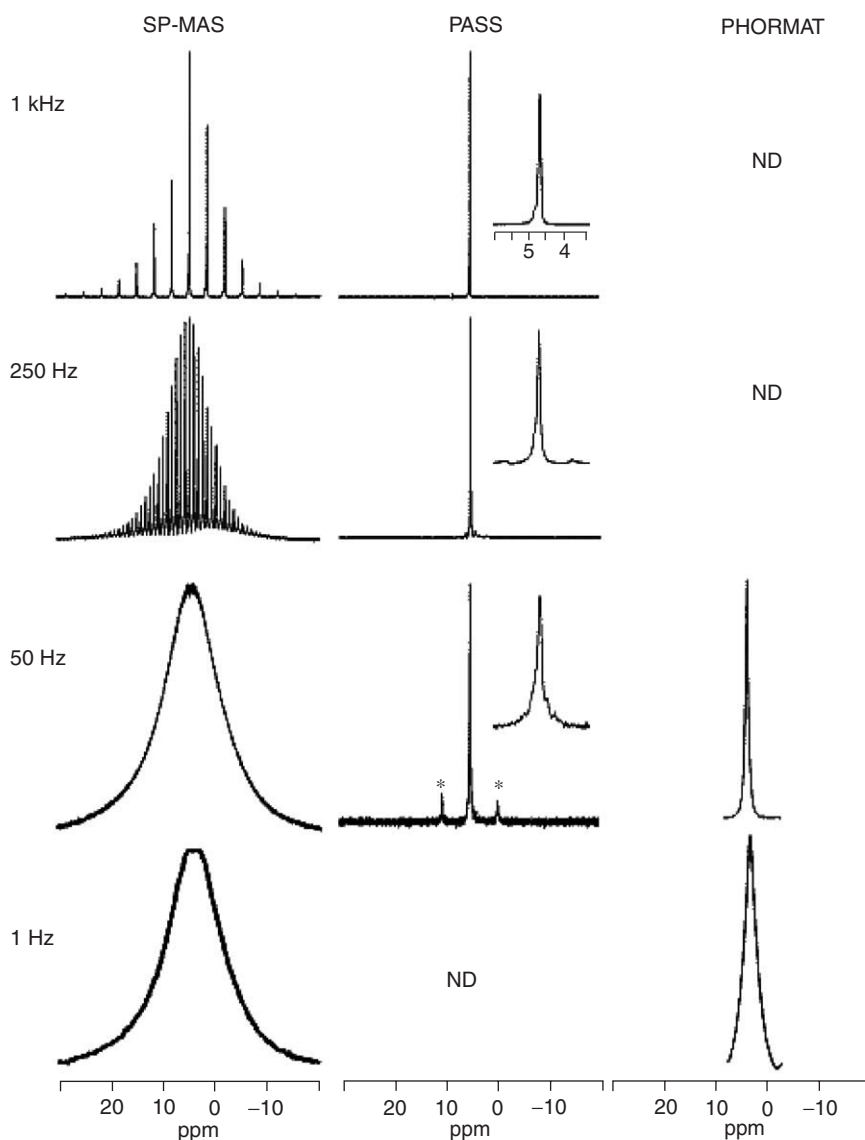

**Figure 4** Top: The water suppressed <sup>1</sup>H 2D-PASS spectra of freshly excised rat liver acquired at a spinning rate of 40 Hz. The external field was 7 T. (A) The stacked 2D plot. shift spectrum at a spinning frequency as low as 50 Hz. (The peaks marked by the symbol “\*” in Figure 5 are aliased sidebands, arising because only 32 evolution increments were used to acquire the

PASS data, whereas at this spinning rate the spectrum contained  $\sim 90$  visible sidebands, requiring at least 90 increments.) Moreover, the isotropic line width observed at 50 Hz is similar to that measured at

**Figure 5**  $^1\text{H}$  MAS spectra obtained at different spinning rates by SP-MAS, PASS, and PHORMAT on a mixture of  $\text{H}_2\text{O}$  and spherical glass beads with diameters of  $230 \pm 20 \mu\text{m}$ . The PASS spectra are the center-band spectra, the PHORMAT spectra are the isotropic projections. (Reprinted with permission from Hu JZ and Wind RA (2002) The evaluation of different MAS techniques at low spinning rates in aqueous samples and in the presence of magnetic susceptibility gradients. *Journal of Magnetic Resonance* 159: 92–100; © Elsevier.)

higher spinning frequencies. However, at this speed the signal is seriously attenuated. This is caused by the decay of the magnetization during the rotor period  $T_r$  prior to the acquisition (cf. Figure 3B). During this period the magnetization dephases in the transverse plane, and is partially refocused by the  $180^\circ$  pulses. Hence, the time constant governing the decay is approximately given by the intrinsic spin-spin relaxation time  $T_2$ , which means that the minimum spinning frequency should be larger than  $(T_2)^{-1}$ , i.e., the isotropic line width, in order to avoid serious signal losses. This has as a consequence that for biological samples, where the minimum

metabolite  $T_2$  values are of the order of 30 ms, with PASS spinning frequencies of  $\sim 40$  Hz or larger should be used.

The  $T_2$  attenuation is avoided in a PHORMAT experiment. Here, the magnetization is stored parallel to the main field direction with a maximum duration of  $2/3$  times the rotor period, which means that the spinning frequency has to be large compared with the spin-lattice relaxation rate  $(T_1)^{-1}$  of the spins rather than  $(T_2)^{-1}$  in order to avoid signal attenuation. Hence, for the water/bead mixture, where the water  $T_1$  is several seconds, the spinning speed can be made as low as 1 Hz without causing

serious signal attenuation, and the same is true for biological samples, where the metabolite  $T_1$  values are at least an order of magnitude larger than the  $T_2$  values. However, it follows from Figure 5 that at ultralow spinning speeds the isotropic line width increases. This is due to the diffusion of the water molecules in the susceptibility gradients. This diffusion-induced broadening, which cannot be eliminated with MAS techniques, is proportional to  $G\sqrt{D/F}$ , where  $G$  is the susceptibility gradient,  $D$  is the diffusion coefficient, and  $F$  is the MAS frequency. It follows that this broadening is much less in biological samples, where both  $G$  and  $D$  are at least an order of magnitude less than in the water/bead mixture. Comparing the SP-MAS, PASS, and PHORMAT experiments of the excised rat liver shown above, it was estimated that the diffusion-induced line broadening in a 1 Hz PHORMAT experiment is  $\sim 2$  Hz at 7 T, considerably less than the intrinsic line width.

Finally, it is worth noting that compared to PASS, PHORMAT has a considerably lower NMR sensitivity and often requires a longer measuring time. The sensitivity loss is mainly due to an intrinsic loss of a factor of 4 resulting from the use of two storage pulses  $p_1$  and  $p_2$  in the PHORMAT sequence, cf. Figure 3C (the storage pulse  $p_3$  is omitted in a regular PHORMAT experiment). Also, PHORMAT often requires a relatively large number of evolution steps, resulting in a long measuring time, an hour or more. Although the performance of PHORMAT can be improved, e.g., by applying multiple-echo acquisition, PASS should be considered as the method of choice if the sample can tolerate spinning speeds of tens of hertz. PHORMAT should be reserved for research in larger biological samples, including *in vivo* applications.

### In Vivo PHORMAT

Two effects associated with spinning a live animal can cause harm: the centrifugal forces induced in the animal, and the effects induced by the external magnetic field, rendered partially time-dependent from the rotating animal's point of view when spinning inside the magnet. This time-dependent field  $dB/dt$  can cause nerve and cardiac stimulations in a similar way as pulsed field gradients. However, both effects can be small in a PHORMAT experiment. For instance, when a mouse is placed in a cylinder with a 1 cm radius, and rotated around the magic angle in a 2 T field and with a spinning speed of 1 Hz, the maximum centrifugal force at the periphery of the animal is 0.04 times the gravitational force  $F_g$ , about two orders of magnitude below the forces applied in

chronic centrifuging experiments, and  $dB/dt$  is  $\sim 10 \text{ T s}^{-1}$ , well below the threshold of  $\sim 90 \text{ T s}^{-1}$  for which nerve stimulations have been reported. In fact, 15 mice were spun in a 2 T field at frequencies up to 8 Hz and for durations up to 60 min without causing any apparent short-term or long-term health effects. Hence, it is possible to use ultraslow PHORMAT for *in vivo* studies on live animals. Figure 6 shows the first result of such an experiment, obtained on the middle section of the body of an (anesthetized) female BALBc mouse between the dotted lines shown in Figure 6A and the arrows shown in Figure 6B. Figures 6C and 6D shows the  $^1\text{H}$  85 MHz water-suppressed metabolite spectra obtained in a stationary mouse and a mouse subjected to 1.5 Hz MAS, respectively. Even in this relatively low field a significant increase in spectral resolution is obtained.

### Future Perspectives

It can be concluded that it is possible to significantly increase the resolution in the proton NMR metabolite spectra in intact biological samples by PASS and PHORMAT. It was found that for small samples, with sizes of a few millimeter or less, where spinning speeds of 40 Hz or more can be tolerated, PASS is the method of choice because of its superior sensitivity and short measuring time. For larger biological samples, including animals, ultraslow-MAS PHORMAT, allowing spinning speeds as low as 1 Hz, has to be used. In a 7 T field with PASS the spectral line widths are reduced by an order of magnitude or more to values determined by the intrinsic  $T_2$ , originating from the various spin-spin dipolar interactions, rendered time-dependent by the molecular motions. With 1 Hz PHORMAT slightly larger isotropic line widths are observed, resulting from the molecular diffusion in the susceptibility gradients. Increasing the spinning speed, if allowed, will reduce this contribution. In external fields larger than 7 T the line width reductions are expected to become even larger, as the residual isotropic line widths are essentially field-independent, whereas the susceptibility broadening increases linearly proportional to the field. Hence, with PASS or PHORMAT the full benefits of high-field NMR are obtained.

It is worth noting that the slow-MAS methodology is a new area of research, and that several further improvements are necessary to make PASS and PHORMAT more viable methods for biochemical and biomedical research. Particularly, specific combinations of RF and pulsed-field-gradient sequences need to be developed so that PASS or PHORMAT spectra can be obtained of a select volume in the sample or the animal rather than the whole sample or

the main part of the body. If these implementations are successful, it can be expected that PASS and PHORMAT will significantly increase the utility of proton metabolite NMR spectroscopy for biochemical and biomedical studies in cells, tissues, organs, and animals.

Finally, the question arises whether the slow-MAS approach will ultimately reach the hospital to investigate patients. Obviously in this case PHORMAT is the only candidate. Although spinning a patient at a frequency of (e.g., 1 Hz) may cause no physical harm, it is likely that it will induce unacceptable stress in many patients. An alternative approach might be to rotate the external magnetic field instead of the patient, either mechanically or electronically, or by rotating both the magnetic field and the patient in opposite directions. In this way the spinning speed of the patient can be reduced. The future will tell whether this approach will become a viable option.

## Nuclear Overhauser Effect

**M P Williamson**, The University of Sheffield, Sheffield, UK

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

The nuclear Overhauser effect (NOE) is a powerful nuclear magnetic resonance (NMR) tool for structure elucidation because it can be used to identify pairs of nuclei that are close together, typically within 0.5 nm (5 Å). The size of the effect is strongly dependent upon the internuclear separation  $r$ ; in optimal cases, it is proportional to  $r^{-6}$ . However, as outlined below, complicating factors often reduce this dependence. We therefore stress throughout that structural analyses that rely on exact quantitative measurements should be avoided, and the NOE is best used in a semiquantitative manner.

The NOE is manifested as a change in the intensity of one resonance when a nearby resonance is partially or fully saturated. The behavior of the NOE differs markedly depending on the size of the molecule studied. In small molecules, the NOE builds up slowly, and is positive (i.e., saturation of one resonance leads to an increase in the intensity of a neighboring one), whereas in large molecules, the NOE builds up much more quickly and is negative. Moreover, in large molecules the NOE can be passed on from one nucleus to its neighbor in a process known as spin diffusion, in a way that does not happen in small molecules. The way that the NOE is applied therefore differs depending on the size of the molecule studied.

### Theory

Each NMR-active nucleus is a dipole: that is, it behaves like a small magnet with north and south

poles. A nuclear dipole has a strong effect on the local magnetic field seen by its neighbor. This effect is orientation dependent and is known as dipolar coupling, and is responsible for the very large linewidths seen in NMR spectra of solids. In solution, dipolar coupling is normally averaged out by molecular tumbling. (There is, however, an increasingly important field of research in which molecules are persuaded to adopt a small degree of residual order, in order to keep some residual dipolar couplings, which can be used very effectively to give orientational information.) The molecular tumbling means that dipolar fields fluctuate widely at rates governed by the tumbling rate of the molecule. The important consequence is that molecular tumbling is a source of nuclear spin relaxation, and is indeed the major source of relaxation in many cases.

The NOE is best understood as a competition between different relaxation pathways. In a system consisting of two spins  $I$  and  $S$ , perturbation of the  $z$  magnetization of  $S$  ( $S_z$ ) away from its equilibrium value  $S_z^0$  results in a change in the  $I$  spin magnetization given by

$$dI_z/dt = -\rho_{IS}(I_z - I_z^0) - \sigma_{IS}(S_z - S_z^0) \quad [1]$$

This equation shows that perturbation of  $S_z$  affects the  $z$  magnetization of  $I$  at a rate  $\sigma_{IS}$ , known as the cross-relaxation rate. In contrast to this,  $I_z$  relaxes back to its equilibrium magnetization at a rate  $\rho_{IS}$ , known as the dipolar longitudinal relaxation rate (which is similar to the spin-lattice relaxation rate  $1/T_1$ ).

The rate constants  $\sigma$  and  $\rho$  are given by

$$\sigma_{IS} = (1/20)K^2[6J(\omega_I + \omega_S) - J(\omega_I - \omega_S)] \quad [2]$$

$$\rho_{IS} = (1/20)K^2[J(\omega_I - \omega_S) + 3J(\omega_I) + 6J(\omega_I + \omega_S)] \quad [3]$$

where  $K = (\mu_0/4\pi)\hbar\gamma_I\gamma_S r_{IS}^{-3}$  and  $J(\omega) = 2\tau_c/(1 + \omega^2\tau_c^2)$ ,  $\mu_0$  is the permeability constant in a vacuum, and  $(\mu_0/4\pi)$  is simply a normalization constant for SI

units;  $\hbar$  is Planck's constant divided by  $2\pi$ ;  $\gamma_I$  and  $\gamma_S$  are the gyromagnetic ratios of  $I$  and  $S$ ;  $r_{IS}$  is the internuclear distance;  $J(\omega)$  is called the spectral density function, and characterizes the power available for relaxation as a function of frequency;  $\omega$  is the frequency of the transition; and  $\tau_c$  is the rotational correlation time, which is approximately the time it takes for a molecule to rotate by one radian.

### Time Dependence of the NOE in a Two-Spin System

Equations [1]–[3] allow us to calculate how the NOE behaves in a two-spin system. As explained in more detail below, there are two main ways of observing NOEs. In the first, one spin  $S$  is perturbed, for example, by a selective  $180^\circ$  pulse: almost all two-dimensional (2D) methods work in a similar way. This results in the buildup of an NOE at adjacent spins  $I$  (Figure 1), with an initial rate given simply by

$$f_I\{S\}(t) = 2\sigma_{IS}t = \zeta r_{IS}^{-6}t \quad [4]$$

where the factor of 2 comes from the inversion of  $S$ , and  $\zeta$  is a constant containing all the nondistance-dependent terms in eqn [2]. (A similar equation, but without the factor of 2, applies for cross-peaks in 2D NOESY experiments.) This allows us to write down a very simple way to measure distances. If there is a known fixed distance in the molecule  $r_{\text{ref}}$ , which has an NOE intensity  $f_{\text{ref}}(t)$ , then any unknown distance can be calculated as

$$r_{IS} = r_{\text{ref}}[f_I\{S\}(t)/f_{\text{ref}}(t)]^{-6} \quad [5]$$

**Figure 1** The time dependence of NOE build-up for an ideal two-spin system with  $\omega\tau_c \ll 1$ , following inversion of  $S$  (solid line) or continuous saturation of  $S$  (dashed line).

This method is widely used to measure internuclear distances, particularly in macromolecules. It is simple to apply, and does not require very accurate measurement of NOE intensities, because of the sixth root, which reduces the error in the calculated distance. However, it is only accurate at very short times after the initial perturbation of  $S$ , as described below, and so is usually applied with wide error margins, by imposing distance restraints as ranges rather than exact distances.

The second method for measuring NOEs, which is only used for studies in small molecules, is to saturate spin  $S$  continuously. The NOE at  $I$  builds up to a steady state (Figure 1), given by

$$f_I\{S\} = (I_z - I_z^0)/I_z^0 = (\gamma_S/\gamma_I)\sigma_{IS}/\rho_{IS} \quad [6]$$

### Dependence on Molecular Tumbling Rate

Equations [2] and [3] show that dipolar relaxation depends strongly on the molecular tumbling rate, because of its dependence on  $J(\omega)$ .  $\rho$  increases steadily with  $\tau_c$ . The magnitude of  $\sigma$  also increases with  $\tau_c$ , implying that for small molecules, where  $\tau_c$  is small, the rate at which the NOE builds up is very slow, while NOEs build up faster in large molecules. However, the sign of  $\sigma$  changes as  $\tau_c$  increases, because  $J(\omega_I + \omega_S)$  becomes less efficient as molecular tumbling slows, whereas  $J(\omega_I - \omega_S)$  becomes more efficient. The maximum achievable steady-state NOE is calculated by substituting eqns [2] and [3] into eqn [6], and is shown in Figure 2, which indicates that the steady-state NOE is positive for small molecules, goes through zero at  $\omega\tau_c \sim 1.12$ , and then becomes negative for large molecules. Note that for very large molecules, where  $\omega\tau_c \gg 1$ , the steady-state NOE is  $-1$ . This implies that saturation of one spin  $S$  will eventually lead to an indiscriminate loss of signal from all the other spins in very large molecules, by a process known as spin diffusion. Although spin diffusion can sometimes be useful, for example, in the

**Figure 2** The dependence of NOE intensity on  $\omega\tau_c$  for an ideal two-spin system following steady-state irradiation of  $S$ .

saturation transfer experiment for mapping intermolecular interfaces, it means that steady-state NOE experiments in large molecules give no useful distance information. This is one major reason why transient experiments such as 2D NOESY and ROESY are almost universally used for large molecules (the other being that selective saturation is nearly impossible in large molecules with crowded spectra).

In real situations, other spins and other sources of relaxation are present, which will increase spin-lattice relaxation rates, and therefore reduce the size of the NOE seen. It is therefore necessary to modify the equations: for example, eqn [6] becomes

$$f_I\{S\} = (\gamma_S/\gamma_I)\sigma_{IS}/(\rho_{IS} + \rho_I^*) \quad [7]$$

where  $\rho_I^*$  represents any other sources of relaxation, which are usually unknown. A common source of relaxation is provided by unpaired electrons, found in transition metal ions and also in dissolved molecular oxygen.  $\rho_I^*$  is often independent of molecular size (whereas  $\rho_{IS}$  is small in small molecules). Consequently, it is a more severe problem when studying NOEs in small molecules, in which cases the size of the NOE can often be increased by removing unpaired electrons, for example, by degassing the solution. Even with such precautions, the NOEs seen in small molecules are often much smaller than predicted by 'ideal' equations, such as eqn [6]. It also means that, for small molecules, with slow NOE build-up rates and more significant external relaxation pathways, transient NOE experiments are slow and give only small NOEs, and it is therefore common to use steady-state experiments. As the molecule gets larger, cross-relaxation rates increase, which makes 2D experiments more attractive.

### The Rotating Frame NOE

Figure 2 shows that there is a molecular tumbling rate ( $\omega\tau_c \sim 1$ ) for which the NOE is very small. Typically, this will occur for molecules with relative molecular masses of  $\sim 1000$ , although the relationship between molecular mass and correlation time is not easily predictable, and depends on other factors such as solvent viscosity and temperature. The rotating frame NOE experiment was developed in order to avoid this difficulty, since in this experiment the NOE is always positive, in fact becoming larger as the correlation time increases. It has a further advantage in that spin diffusion is much less of a problem than in conventional NOE experiments, and it is therefore used widely for intermediate sized molecules, often in its 2D form, known as ROESY or HOHAHA. For large molecules, it is slightly less sensitive and more prone to artifacts than NOESY,

but can still be a useful alternative particularly where spin diffusion is thought to be important.

### Multispin Systems

So far we have only considered two-spin systems. We now consider the effect of additional spins, and again it is convenient to divide the discussion into (1) large molecules, with  $\omega\tau_c \gg 1$ , studied using NOESY, and (2) small molecules, with  $\omega\tau_c < 1$ , studied using 1D steady-state techniques.

**Large molecules: spin diffusion** We consider the effect of a third spin ( $X$ ) on the buildup of the NOE between two protons  $I$  and  $S$ , as would be observed in a transient or 2D NOE experiment. The buildup can be calculated by adding an extra term to eqn [1], which is then solved either by numerical integration of the equation, or by matrix algebra, the so-called 'relaxation matrix' approach. The results show that when  $S$  is inverted, and  $X$  is distant from  $I$ , no effect is seen on the buildup. In a linear arrangement  $S-I-X$ , as  $X$  gets closer to  $I$ , it helps to relax  $I$ , and so the NOE at  $I$  decays sooner than it would otherwise do. At the same time, an NOE is seen building up at  $X$ . On a naive 'two-spin' interpretation, this would appear to imply that  $X$  is closer to  $S$  than it really is. This is the effect commonly known as spin diffusion, in which the NOE 'diffuses' outwards from the site of irradiation; it makes the interpretation of NOE intensities complicated, especially at longer NOE build-up times when the NOE has had more time to diffuse, and is a major problem in the quantitative interpretation of NOE intensities. For a known geometry, the effect can be calculated exactly, but for an unknown geometry, it is hard to spot. The effects of spin diffusion are normally minimized by keeping the NOE build-up time as short as practicable.

**Small molecules** In small molecules (and in ROESY for any size of molecule) spin diffusion also occurs, but its consequences are altered because the third spin ( $X$  in the linear  $S-I-X$  example) now receives a negative NOE, by contrast to the normal positive NOE seen at  $I$ . This is known as a three-spin effect, and is much easier to spot than spin diffusion in large molecules, because of the change in sign of the NOE. In addition, because the maximum positive NOE is  $+0.5$  (Figure 2), the magnitude of the three-spin effect can never be bigger than  $0.5^2 = 0.25$  and is usually much smaller, and the subsequent (positive) four-spin effect (e.g.,  $S$  to  $Y$  in  $S-I-X-Y$ ) is very rarely observed. By contrast, four-spin spin diffusion pathways in large molecules are readily observed.

If the  $S-I$  distance is kept fixed, and  $X$  is rotated around  $I$  to become closer to  $S$ , it starts to receive a

direct (positive) NOE in addition to the indirect negative NOE. For certain geometries, it is thus possible for the  $X\{S\}$  NOE to be very small, even if the  $S-X$  distance is quite short. Once again, distance calculations using the NOE are seen to be not straightforward, even though they may be strongly dependent on distance! It should be noted, however, that NOEs can, in principle, be calculated exactly, for any number of spins (given all the appropriate motional and relaxation parameters, which in practice are not experimentally accessible). The difficulties inherent in using the NOE to derive distances have been emphasized here because of the widespread over-interpretation of NOEs to produce quite erroneous and unrealistically precise distances.

### Distance Calculation

**Large molecules** As outlined above, in principle the NOE at short build-up time is directly proportional to  $r^{-6}$ . However, at times short enough to be certain of the proportionality (i.e., such that spin diffusion should not have got very far), the NOE may be so small as to be almost unobservable. One must therefore work at slightly longer build-up times (of the order of 100 ms), and accept some error in the derived distance, particularly for weaker NOEs. This is achieved by specifying NOE-derived distances as ranges, rather than single distances, with the size of the range larger at longer distance. The reference distance is best obtained from known intramolecular distances of similar distances to the target: for example, by calibrating the strongest sequential  $C\alpha H-NH$  NOE in a protein to 0.23 nm, the shortest possible distance for such an NOE.

**Small molecules** Small molecules are generally studied using steady-state techniques. The resulting intensity effects can therefore involve several spins, and can be quite complex. For example, steady-state NOEs are not symmetrical – in other words, the NOE at A on saturation of B is not equal to the NOE at B on saturation of A, since the NOEs depend on the other neighbors of the spins observed. It is still usually true that NOEs to nearby protons are large, while NOEs to distant protons are small, but this is not universally true; for example, an NOE to a distant but isolated proton can be very large, as it has no competing relaxation pathways to reduce the NOE. Analytical equations can be written down for any given spin system, however complex, but rapidly become unwieldy. In practice, a complete analysis is seldom attempted, and the normal practice is to limit analysis to a qualitative survey, as described below.

A general problem with the derivation of distances from NOEs is intramolecular motion. Motion can

both alter the local correlation time and also alter internuclear distances. Because the cross-relaxation rate is  $r^{-6}$ -dependent, motions that allow two nuclei to become close together some of the time give rise to a disproportionately large NOE. Indeed, local motions can result in patterns of NOEs that are incompatible with any single static structure. This is another reason for caution in the quantitative interpretation of NOEs.

### Heteronuclear NOEs

The dipole–dipole cross-relaxation mechanisms that give rise to homonuclear NOEs can just as easily produce heteronuclear NOEs. The heteronuclear NOE is often used to increase the intensity of the heteronuclear signal. For example, saturation of protons during acquisition of  $^{13}C$  spectra gives rise to an NOE on carbon of just under 2 (eqn [6]). Thus, the net intensity of carbon signals in small molecules is up to three times greater than it would be without the NOE.

As in the homonuclear case, the NOE is reduced by competing relaxation mechanisms. If a carbon atom has a proton attached, its relaxation is dominated by dipole–dipole relaxation from the proton, whereas for quaternary carbons, dipolar relaxation is slower, and competes less effectively with other relaxation pathways, often producing a reduced NOE. The size of the NOE also depends on the correlation time, and, like the homonuclear NOE, changes markedly around  $\omega\tau_c \approx 1$ . Most heteronuclear NOEs become very small for large molecules; the only common exception is the  $^{19}F\{^1H\}$  NOE, which behaves very similarly to the  $^1H\{^1H\}$  NOE. Nuclei with negative gyromagnetic ratio, such as  $^{15}N$ , have negative NOEs. This can lead to loss of signal if the NOE is only partial and is close to  $-1$ . The properties of the more common nuclei are listed in Table 1.

The heteronuclear NOE can be used as a structural tool, by irradiating specific protons individually and measuring NOEs to nearby heteronuclei. Because

**Table 1** NOE characteristics of common nuclei

Nucleus	Gyromagnetic ratio, $\gamma$ ( $10^7 \text{ rad T}^{-1} \text{ s}^{-1}$ )	Maximum $f_X\{^1H\}^a$	
		$\omega\tau_c \ll 1$	$\omega\tau_c \gg 1$
$^1H$	26.75	50	–100
$^{13}C$	6.73	199	15.4
$^{15}N$	–2.71	–494	–21.7
$^{19}F$	25.18	53	–104
$^{31}P$	10.84	123	2.2

<sup>a</sup>Maximum % NOE obtainable in a steady-state experiment, listed for the extremes of small and large molecules.

heteronuclear relaxation is dominated by directly bonded protons, the only structurally useful heteronuclear NOEs are to atoms with no protons attached.

Heteronuclear NOEs are also widely used to characterize mobility. In particular, the  $^{15}\text{N}\{^1\text{H}\}$  NOE is very small for  $\omega\tau_c \gg 1$ , but goes to almost  $-5$  for fast tumbling. (The literature for heteronuclear NOEs is confusing, in that it is common to describe the NOE as relative intensity rather than relative enhancement, which results in NOE values larger by one than the enhancements used normally.  $^{15}\text{N}\{^1\text{H}\}$  NOEs on this definition range from  $-3.9$  to  $0.8$ , rather than  $-4.9$  to  $-0.2$ .) Proteins generally have  $\omega\tau_c \gg 1$  for all backbone N-H vectors, giving rise to small NOE enhancements. However, if the backbone is locally mobile, the NOE becomes

more negative. Measurement of the NOE provides a simple measure of local mobility, and is often combined with measurements of  $^{15}\text{N}$   $T_1$  and  $T_2$  for a more quantitative assessment.

## NOE Experiments

For large molecules, the 2D NOE experiment NOESY is universally used. It is easy to set up and analyze, and very reliable. The only parameter that requires thought is the mixing time, during which the NOE builds up. Shorter values (e.g., 50 ms) reduce spin diffusion, but also reduce sensitivity. Times longer than  $\sim 200$  ms are not useful for large molecules, because spin diffusion becomes too severe, and sensitivity gain is not significant.

**Figure 3** NOE experiments recorded using a  $20\text{ mmol l}^{-1}$  sample of  $11\beta$ -hydroxyprogesterone in  $\text{CDCl}_3$  using a Bruker DRX500 spectrometer.  $H_{11z}$  was irradiated. (A) Conventional 1D spectrum. (B) Standard steady-state difference spectrum, 5 s saturation time. Note the subtraction artifacts, particularly at the intense methyl singlets at 0.8, 1.4, and 2.1 ppm. (C) Double pulsed field gradient spin echo NOE spectrum, 1 s NOE evolution period. The spectrum is essentially free of artifacts, and permits the observation of an enhancement at  $Me_{19}$  and possibly  $Me_{18}$  that could not reliably be detected in the conventional experiment. The signal marked \* is an intermolecular enhancement to  $\text{H}_2\text{O}$  dissolved in the  $\text{CDCl}_3$  presumably transmitted via exchange from  $OH_{11}$ . (Reproduced with permission from Stott K, Ph.D. Thesis. University of Cambridge, UK.)

For medium-sized molecules (molecular weight 500–1000), the ROESY experiment is most common. This again is easy to set up, though it does require slightly more care because the continuous power during the NOE build-up time leads to sample heating and can damage the hardware if applied at too high a power.

The choice of experiments is most difficult with small molecules. The standard experiment is the steady-state NOE, in which specific low-power saturation is applied for 5 s or more, and a control spectrum is subtracted. The experiment can be speeded up with little loss in sensitivity (but a reduction in quantitative information) by reducing the saturation time to 1–2 s. This is a difference experiment, and always contains experimental artifacts, resulting from incomplete subtraction of reference signals. A few years ago, a gradient-enhanced experiment was proposed, which has lower absolute sensitivity but much smaller artifacts, and is therefore gradually taking over as the experiment of choice. It requires a spectrometer with reliable pulsed field gradient hardware, but once set up, is as simple and reliable as steady-state experiments, and produces exceptionally clean NOE spectra, allowing the observation of very small enhancements (Figure 3).

## Use in Structure Determination

The widespread use of the NOE in structure determination is a consequence of its strong dependence on distance; that is, NOEs are used to define approximate distances, and the distances are then used to generate structures compatible with these distances. In large molecules, the relationship between NOE intensity and distance is reasonably strong, facilitating such methods as distance geometry and simulated annealing, which directly use distance information to restrain structures. In small molecules, the NOE is more effective when giving qualitative rather than quantitative information. Thus, if the mere presence of an NOE can be used to distinguish between two structures, the NOE is a reliable tool, whereas if the size of an NOE is being used to fix the conformation of a molecule, great care is necessary, and use of other information, for example, coupling constants, is preferred.

### Small Molecule Structure Determination

Substitution patterns around aromatic rings form a good subject for analysis using the NOE, since the information required is almost entirely of a qualitative nature. For example, a condensation reaction produced a compound that was expected to have

structure [I] or [II]. Saturation of the H<sub>5</sub> protons produced a strong (24%) NOE at H<sub>7</sub>, thereby identifying the compound as [I].

[I]

[II]

Stereochemical problems can often be solved very simply using the NOE, but only in more or less rigid systems. Thus, fused ring systems can often be analyzed in a straightforward manner, because such systems are frequently rigid enough for study using the NOE (e.g., Figure 3). The fungal neurotoxin penitrem A [III] was characterized by <sup>1</sup>H and <sup>13</sup>C NMR, and most of the covalent structure was pieced together using (<sup>13</sup>C, <sup>1</sup>H) and (<sup>13</sup>C, <sup>13</sup>C) spin-spin coupling connectivities. At this point, the NOE was used to obtain stereochemical information. This molecule is much larger than [I], but in organic solvents such as perdeuterated acetone it still tumbles rapidly enough to give positive NOEs, and has a spectrum with enough spectral dispersion that all protons can be selectively irradiated. The result of a large series of steady-state experiments is shown in the structure of [III]. The NOEs unequivocally give the relative stereochemistries of all groups in the molecule, which is only possible because of the rigid ring junctions that fix most of the internuclear distances.

Conformational details in more mobile systems are harder to derive, as they rely on accurate quantification, and require a number of assumptions to be made. A study was made of the conformation of the dienyl side chain of [IV]. On the basis of the exanomeric effect, the diene fragment would be expected to adopt one or both of the conformations [IVA] or [IVB]. Note that there is no direct evidence from NMR for these conformations; because NMR

signals are time-averaged, only a single resonance is observed for each nucleus, and all the observed NMR parameters are weighted averages. Irradiation of H<sub>1'</sub> produces a 13% enhancement at H<sub>1</sub> and a 4% enhancement at H<sub>2</sub>. This suggests that both rotamers are present, and that the major rotamer is [IVA]. Any more quantitative assessment would rely on the 'model' conformations [IVA] and [IVB] being correct, and would also require detailed measurements of relaxation rates for all the protons involved, as well as assumptions as to rotation rates and relaxation mechanisms.

**Figure 4** Part of the NOESY spectrum of the C-terminal half of rat testis calmodulin. (A) 2D NOESY spectrum, mixing time 200 ms. (B) A plane from the 3D  $^{15}\text{N}$ -resolved NOESY spectrum, taken at a  $^{15}\text{N}$  frequency of 127.04 ppm. Note the greatly improved resolution and the high signal-to-noise ratio of spectrum (B). (*Natural Product Reports* (1993) 10: 207–232; reproduced by permission of The Royal Society of Chemistry.)

$r^{-6}$  dependence of the NOE at short mixing time, and protocols for the application of distance constraints in distance geometry or simulated annealing calculations are becoming standardized. Often the biggest problem in analyzing NOESY spectra of proteins is the chemical shift degeneracy of protons, which makes it impossible to provide confident assignments for the cross-peaks. It is therefore common to label proteins with  $^{15}\text{N}$  and  $^{13}\text{C}$ , and to use the chemical shifts of the labels to help to resolve degenerate  $^1\text{H}$  signals, using 3D and 4D  $^{15}\text{N}$ - and  $^{13}\text{C}$ -resolved spectra (Figure 4). As noted in the previous section, motion is one of the hardest problems to deal with, because the observed NOEs are highly nonlinear averages.

Intermolecular NOEs have been very useful for defining the geometry of complexes, including those of protein dimers. Differential heteronuclear labeling of the two components of a dimer is often

used to distinguish intramolecular from intermolecular NOEs.

### The Transferred NOE

The transferred NOE is a technique used to obtain structural information on the conformation of a small ligand bound to a much larger receptor, such as a protein. It relies on the fact that the cross-relaxation rate for a free ligand is slow, whereas for the bound ligand it is much faster. If the ligand is in exchange between free and bound states, any NOE built up in the bound state will be transferred to the free state by exchange processes. The observed average cross-relaxation rate  $\langle\sigma_{IS}\rangle$  is

$$\langle\sigma_{IS}\rangle = P^F\sigma_{IS}^F + P^B\sigma_{IS}^B \quad [8]$$

where  $P^F$  and  $P^B$  are the relative populations of the free and bound states, and  $\sigma_{IS}^F$  and  $\sigma_{IS}^B$  are their cross-relaxation rates. Because  $\sigma_{IS}^B$  is much greater than  $\sigma_{IS}^F$ , it is possible (and usual) to have a 5- to 20-fold excess of free over bound states ( $P^F/P^B = 5\text{--}20$ ), and still observe only the cross-relaxation in the bound state. The experiment is most commonly carried out as a 2D NOESY experiment, where the intensities of NOESY cross-peaks, observed at the frequencies of the free resonances, give information on distances in the bound state (Figure 5).

### Introduction

Modern nuclear magnetic resonance (NMR) spectroscopy is carried out in the pulse-Fourier transform mode. This is achieved by applying a short intense pulse of radiofrequency (RF) power to a sample and monitoring the decaying voltage induced in a receiver coil as nuclei excited by this RF pulse relax back to equilibrium. This signal, known as free induction decay (FID), is related to the conventional NMR spectrum by the Fourier transform. This type of NMR spectroscopy is termed one-dimensional (1D) NMR because the signal is collected for a single acquisition time and this signal, after Fourier transformation, results in a spectrum of signal intensity as a function of a single frequency axis.

In many molecular systems such as proteins and other macromolecules, or in multicomponent mixtures such as biofluids, the spectral complexity and signal overlap in 1D NMR spectra can be too great for simple assignment of NMR resonances. Under these circumstances, it would be desirable to improve the dispersion of the signals. One approach is to simplify the complex 1D NMR spectrum to leave only resonances that are amenable to interpretation by the use of special pulse sequences. These can edit the original spectrum into subsets of data, or excite or detect only specific types of resonances; for example, only those that are spin-spin coupled to a given resonance. These latter experiments use longer, lower power pulses termed selective pulses. An alternative approach is to achieve this dispersion is through the use of 2D or higher dimensional ( $n$ D) methods. The pulse sequences that form the basis of such multidimensional NMR approaches not only enable increased spectral dispersion, but can also have the added advantage of giving information on relationships between the various resonances in the spectrum; for example, showing which ones are coupled to each other by spin-spin coupling.

There are numerous examples of the application of multidimensional NMR spectroscopy in disparate areas of study, and some idea of the breadth of such NMR experiments can be gleaned from the Specialist Periodical Report on NMR spectroscopy from the UK's Royal Society of Chemistry.

### Principles of 2D NMR

As an alternative to the specific solutions that are available in 1D NMR, the general approach adopted in 2D NMR is to apply a series of RF pulses to the sample such that there are two independent variable time intervals in the pulse sequence. One of these is the acquisition time, denoted by  $t_2$ , and the other is some incremental delay denoted  $t_1$ . If an NMR FID is acquired for a period  $t_2$  for each of a set of  $t_1$  values, the digital NMR signal intensity ( $S$ ) will be a function of both  $t_1$  and  $t_2$  giving a matrix of data  $S(t_1, t_2)$ . If Fourier transformation is carried out with respect to both  $t_1$  and  $t_2$  a matrix of NMR intensity as a function of two frequencies will result. This is now a 2D NMR spectrum as it represents signal intensity as a function of two frequency axes. The delay  $t_1$  and the actual nature of the pulse sequence will, as may be seen later, define exactly what the two frequency axes will represent. As a consequence of this process, there are two immediate benefits: increased signal dispersion and hence less overlap, and if the experiment is conducted in certain ways, it is possible to evaluate connectivities between the various NMR resonances. On the other hand, the 2D approach usually requires increased experiment time and increased computer data storage requirements.

Adding more independent incremental delays to the pulse sequence followed by corresponding Fourier transformation steps leads to further increases in frequency dimensionality to yield 3D NMR, 4D NMR, and so on. A number of 3D and 4D experiments have found use, particularly in the assignment of the complex spectra that arise from proteins and carbohydrates.

### Definition of a 2D NMR Experiment

A 2D NMR experiment contains up to five separate elements. These are:

1. A preparation period, consisting of RF pulses and possibly delays, after which the nuclei are in some defined nonequilibrium spin state.
2. An evolution period of length  $t_1$  during which the properties of the nuclei such as chemical shifts or coupling constants are allowed to evolve at their appropriate frequencies. It is this period that is incremented in the 2D NMR experiment.
3. A mixing period that can comprise further RF pulses and delays during which information is

transferred between the nuclei in specific ways. This mixing period will have a different effect on the final detected signal according to the value of  $t_1$ . Not all 2D NMR experiments require a mixing period.

4. A detection period of length  $t_2$  during which the FID is acquired.
5. A relaxation period to ensure that the spin system is at equilibrium before the next cycle of acquisition.

The actual procedure is to obtain successive FIDs each for a time period of  $t_2$  using  $n_2$  data points for each increment in the value of  $t_1$ , with the first value being very short and increasing in equal steps for a total of  $n_1$  steps. Thus, the data matrix consists of ( $n_1 \times n_2$ ) data points. After data acquisition, the  $n_1$  FIDs are Fourier transformed in the normal way to give  $n_1$  spectra in a data matrix  $S(t_1, \omega_2)$ , one for each value of the evolution period  $t_1$ . The data are then transposed by taking corresponding points in each spectrum (i.e., all of the first points in the original  $n_1$  spectra are put into a new representation to give a spectrum of  $n_1$  points, this process being repeated until there will be  $n_2$  such spectra). These transposed spectra are called interferograms and the data matrix is now  $S(\omega_2, t_1)$ . A Fourier transformation with respect to  $t_1$  gives the final 2D NMR spectrum  $S(\omega_2, \omega_1)$ .

The FIDs and interferograms can be multiplied by appropriate mathematical functions before Fourier transformation in order to improve sensitivity, resolution, or line shape exactly as in 1D NMR. The NMR data are usually obtained as two separate components  $90^\circ$  out of phase from each other in a mode called quadrature detection to yield two spectral components denoted real and imaginary. A suitable linear combination of these two components allows the generation of a spectrum with a pure absorption phase. In 2D NMR, this phase-sensitive detection sometimes results in line shapes and phases that do not allow a pure absorption spectrum to be obtained and then the compromise of a magnitude mode presentation is used. This comprises the square root of the sum of the squares of the real and imaginary components and is wholly positive. Usually, 2D NMR spectra are plotted as contour maps as though the 2D spectral peaks are a series of mountains viewed from above relative to the orthogonal  $\omega_1$  and  $\omega_2$  axes.

There are basically two types of 2D NMR experiments. These are termed (1) resolved and (2) correlated, according to the type of dispersion in the second frequency dimension  $\omega_1$ . Resolved experiments are a way of improving spectral dispersion

by rotating the appearance of one NMR parameter at right-angles to another so that the  $\omega_1$  and  $\omega_2$  axes correspond to different parameters. The commonest version of this is to cause the rotation of all spin-spin coupled multiplets by  $90^\circ$ , thus producing only chemical shifts along the  $\omega_2$  axis and at each chemical shift the spin-spin coupled multiplet is spread along the  $\omega_1$  axis. Generally, no information is available from a resolved experiment on the spin-spin coupling connectivity between resonances. The other class of proton 2D NMR experiment, the correlated type, provides information on connectivity between resonances such as those that have a common spin-spin coupling or arise from nuclei that are close together in space. In these cases, for identical nuclei, the  $\omega_1$  and  $\omega_2$  axes are identical.

There have been many multidimensional NMR experiments published for homonuclear  $^1\text{H}$ - $^1\text{H}$  studies and for  $^1\text{H}$ -heteronuclear studies as well as others involving heteronuclei only. Many are variations of general schemes for specific applications and only a few 2D NMR experiments have become widely used. The following sections discuss these principal 2D NMR experiments and the reader is referred to the Further Reading section for specific details of the theory and practical aspects of multidimensional NMR.

There are further classes of experiment that result in pseudo-2D NMR spectra. These do not have a second frequency axis resulting from Fourier transformation of a variable time, but the second axis is some other parameter. One example is provided by continuous-flow directly coupled HPLC-NMR spectra where the second axis in the pseudo-2D plot is the chromatographic retention time. Another example is diffusion-ordered NMR spectroscopy where the second axis plots the molecular diffusion coefficient associated with each NMR peak, this parameter being derived from the dependence of peak intensities on the square of an applied magnetic field gradient.

## Resolved Experiments

The principal pulse sequence in the resolved experiment category for high-resolution solution-state NMR is the  $J$ -resolved experiment (JRES). It is based on the spin-echo pulse sequence in which the delay between the  $90^\circ$  and  $180^\circ$  pulses is incremented as the evolution period  $t_1$ , and so the pulse sequence is

$$-\text{RD} - 90^\circ - t_1 - 180^\circ - \text{ACQ}(t_2) -$$

where RD is a relaxation delay and ACQ( $t_2$ ) is the data acquisition period. The spin-echo sequence leads to the elimination of the effects of chemical shifts during the period  $t_1$ , but spin-spin couplings cause a phase modulation of the NMR signals to a degree that is dependent on the length of  $t_1$ . The two Fourier transform steps therefore produce a 2D NMR spectrum with both chemical shifts and spin-spin couplings on the  $\omega_2$  axis at their normal frequency positions, but only the couplings appear on the  $\omega_1$  axis. In fact, the pulse sequence results in multiplets that appear at an angle of  $45^\circ$  relative to the axes and a representation is usually shown in which these multiplets have been further tilted by  $45^\circ$  to make them orthogonal to the  $\omega_2$  axis. Under these circumstances, the projection of the spectrum on to the  $\omega_2$  axis produces a  $^1\text{H}$  NMR spectrum consisting of singlets at each  $^1\text{H}$  chemical shift, i.e., a fully proton-decoupled proton NMR spectrum. The results are not so clear-cut if the spin system is not first order; in this case additional lines appear at the average  $\omega_2$  position of the strongly coupled nuclei. However, the JRES experiment can be a very useful aid to the assignment of resonances in the complex spectra that arise from mixtures of small molecules such as biofluids where many of the individual components give first-order spectra. Also, because the JRES experiment is based on the spin-echo sequence, any nuclei with short  $T_2$  values will relax within the  $t_1$  evolution period and not contribute to the final spectrum. This has proved useful for the analysis of blood plasma by proton NMR as the broad, short  $T_2$  resonances from proteins and lipoproteins are greatly suppressed. Any heteronuclear couplings such as those between protons and fluorine nuclei will not be rotated into the  $\omega_1$  axis as the lines act as though they are chemically shifted. These couplings therefore appear separated on the  $\omega_2$  axis. In the IRES experiment, the spectrum is calculated as the magnitude presentation after the second Fourier transform because the tilted phase-sensitive spectrum has zero intensity on the  $\omega_1$  axis. In order to overcome the adverse line shape that results in magnitude mode spectra, appropriate resolution enhancement is usually carried out in the time domain before Fourier transformation. There is a corresponding heteronuclear experiment, usually for  $^{13}\text{C}$  NMR, where the  $^{13}\text{C}$ - $^1\text{H}$  coupling patterns for each resonance are rotated into the  $\omega_1$  dimension.

The various proton 2D NMR experiments are illustrated using dexamethasone dissolved in DMSO- $d_6$  solution and measured at an observation frequency of 600 MHz. Dexamethasone has the molecular structure and numbering system given below.

Figure 1 shows the partial 600 MHz  $^1\text{H}$  JRES NMR spectrum of dexamethasone in the region from  $\sim\delta 0.7$  to  $\delta 3.0$ . This expansion excludes the resonances from the olefinic hydrogens H1, H2, and H4, the signals from the deshielded aliphatic hydrogens H11a, H21, and H21', and the resonances from OH protons. In the 2D NMR contour plot, the multiplet nature of each resonance is resolved at right angles to the  $\omega_2$  axis. Some artifacts can be seen, particularly close to the large peaks. These probably arise from the tilting and symmetrization manipulation of the data. Plotted above the 2D spectrum is the projection of the peaks on to the  $\omega_2$  axis to give a resonance at the chemical shift of each proton. It should be noted that these projections show a wide variation in intensity that cannot be directly related to the number of protons contributing to the multiplet.

## Correlation Experiments

### Resonance Correlation via Spin-Spin Coupling

The proton homonuclear experiment, termed COSY (COReletion Spectroscopy), serves to show which resonances in a proton spectrum have mutual spin-spin couplings. The method works for a wide range of coupling constant values and can be carried out in magnitude mode or phase-sensitive mode. It has largely replaced the conventional 1D NMR single-frequency spin-decoupling approach because it gives all connectivities in one experiment, albeit at the expense of longer acquisition times and a requirement for large data matrices. The pulse sequence is

$$-\text{RD} - 90^\circ - t_1 - 90^\circ - \text{ACQ}(t_2) -$$

and the resulting spectrum has the conventional 1D NMR spectrum along the diagonal and off-diagonal cross-peaks at chemical shifts corresponding to pairs of coupled nuclei. The phases of the RF pulses are changed in a systematic fashion in concert with the phase of the receiver in order to suppress unwanted

**Figure 1** Partial 600 MHz  $^1\text{H}$   $J$ -resolved NMR spectrum of dexamethasone in  $\text{DMSO-d}_6$ . The region from  $\delta 0.7$  to  $\delta 3.0$  is shown. This expansion excludes the resonances from the olefinic hydrogens H1, H2, and H4, the deshielded aliphatic hydrogens H11a, H21, and H21', and the resonances from OH protons. The assignments are as marked.

artifacts and features in the spectrum. As stated above, the experiment is sensitive to a wide range of spin couplings and may result in cross-peaks even in situations where the mutual coupling, although present, cannot be resolved. It is also useful for discovering connectivities to resonances buried in a complex overlap of many bands. To overcome problems of line shape in the 2D NMR spectrum, especially on older spectrometers, it was conventional to produce a magnitude mode spectrum because the phase-sensitive detected signals had a phase-twist line shape from which in-phase absorption signals could not be obtained. This magnitude calculation results in an all-positive spectrum. In order to overcome the adverse line shape effects on resonances near the diagonal peaks, the COSY-45 variation was introduced:

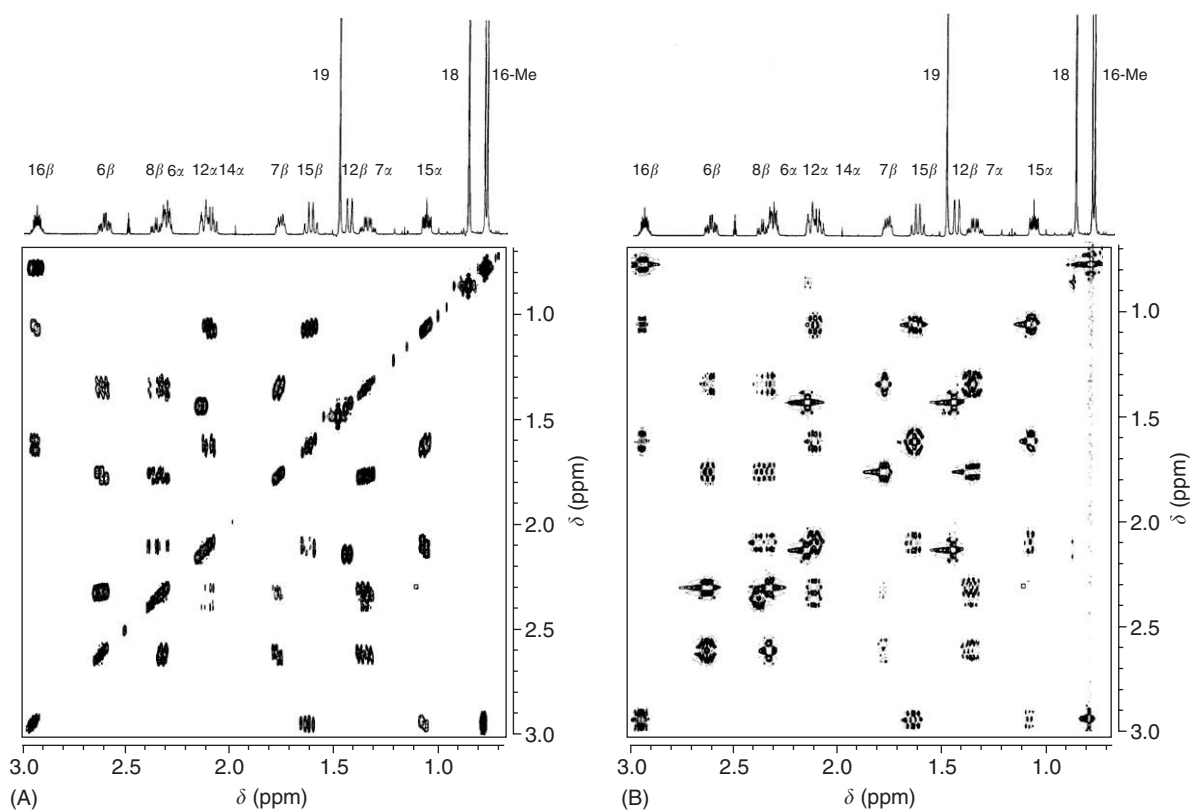

$$-\text{RD} - 90^\circ - t_1 - 45^\circ - \text{ACQ}(t_2) -$$

The reduction in the second pulse width has the principal effect of reducing the intensity of the diagonal relative to the cross-peaks and leaving the cross-peaks with a simpler structure (for three-spin systems or greater). This means that assignments

in crowded regions of the spectrum or close to the diagonal become easier.

However, on modern spectrometers, the COSY experiment is now carried out in phase-sensitive mode through the use of one of two modifications introduced to achieve quadrature detection in the  $t_1$  axis, as well as in  $t_2$  which is done conventionally. These two approaches are called the States-Haberkorn method and time proportional phase incrementation; readers are referred to the Further Reading section for details.

**Figure 2A** shows the COSY-45 2D NMR spectrum of dexamethasone acquired using magnetic field gradients rather than phase cycling (see later). This spectrum is plotted using a magnitude-mode presentation. Again only the region between  $\delta 0.7$  and  $\delta 3.0$  is shown and the assignments are given on the 1D NMR spectrum plotted across the top at the same expansion. A cross-peak can be observed at the chemical shifts of each pair of coupled protons. A modification to the COSY sequence called COSYLR is possible, which is better suited to elucidating connectivities through small- or long-range spin couplings. This is achieved by introducing an additional fixed delay within the evolution period  $t_1$ .

**Figure 2** (A) Partial 600 MHz  $^1\text{H}$ – $^1\text{H}$  COSY-45 NMR spectrum of dexamethasone in  $\text{DMSO-d}_6$  acquired using magnetic field gradients and presented in magnitude mode. The region from  $\delta 0.7$  to  $\delta 3.0$  is shown. (B) Partial 600 MHz  $^1\text{H}$ – $^1\text{H}$  DQF-COSY NMR spectrum of dexamethasone in  $\text{DMSO-d}_6$  acquired using magnetic field gradients and presented in phase-sensitive mode. The region from  $\delta 0.7$  to  $\delta 3.0$  is shown. The vertical bands are common artifacts (called  $t_1$  noise) which appear on high intensity peaks and arise as a consequence of the method of data acquisition.

### Double Quantum Filtered COSY

The double quantum filtered COSY (DQF-COSY) approach causes the suppression of diagonal peaks arising from singlets (i.e., resonances without any spin couplings, or nuclei not part of a multiple spin or multiple quantum system) and allows the cross-peaks to be in pure absorption mode. This simplifies complex spectra and improves resolution. The pulse sequence is modified from the COSY sequence by the inclusion of a short fixed time delay  $\Delta$  as shown:

$$-\text{RD} - 90^\circ - t_1 - 90^\circ(\phi_1) - \Delta - 90^\circ(\phi_2) - \text{ACQ}(t_2) -$$

The third  $90^\circ$  pulse filters out signals that are not spin–spin coupled, i.e., those that cannot be part of a double or higher quantum system. The term  $\phi$  is used to denote that the phases of the  $90^\circ$  pulses are changed in a systematic way to produce this singlet resonance suppression by appropriate addition and subtraction of the received signal on successive scans and the fixed delay  $\Delta$  (10–20  $\mu\text{s}$ ) is included to allow time for the necessary phase switching.

Figure 2B shows the 600 MHz DQF-COSY spectrum of dexamethasone, now acquired and presented

in phase-sensitive mode, with positive contours given full lines and negative contours given dotted lines. Again cross-peaks are observed between coupled protons, but the singlets from the methyl groups are now absent from the spectrum and the coupling patterns of the cross-peaks can be used to determine which is the actual coupling (i.e., that between the protons giving rise to the cross-peak) and passive couplings (i.e., from either of the coupled protons to other protons).

Refinements of the technique can be used which eliminate all resonances from one- and two-spin systems, i.e., singlets and doublets (triple-quantum filtered COSY), and so on for higher-spin systems. The DQF-COSY experiment is not as sensitive as the normal COSY approach and the higher quantum filtering is usually achieved using pulse phase cycling with increments in phase angles of less than  $90^\circ$ , a facility not always available on older spectrometers.

### Total Correlation Spectroscopy

This very powerful experiment, called TOCSY, provides information on unbroken chains of coupled

protons in one 2D NMR spectrum. The experiment is sometimes also called the homonuclear Hartmann–Hahn experiment. The results are not very dependent on the magnitude of the spin–spin couplings involved in the spectrum and all of the peaks are in phase, in absorption mode. The pulse sequence is

$$-\text{RD} - 90^\circ - t_1 - [\text{spin lock}] - \text{ACQ}(t_2) -$$

The method relies on the application of a spin-lock field, which causes the nuclear magnetizations to precess about this RF field, i.e., the spins are said to be locked to this field. During this period, transfer of magnetization occurs between coupled spins. The longer the spin-lock period is applied, the further the magnetization will be transferred down a chain of coupled nuclei. The most widely used spin-lock sequence is based on a train of pulses called MLEV-17. The pulse sequence is identical to that for the ROESY experiment for measuring nuclear Overhauser effects (NOEs) (see later) and it is possible for NOE effects to appear as cross-peaks, which may cause confusion. However, there are means of minimizing these effects.

## 2D Nuclear Overhauser Effect NMR

This is a very useful 2D NMR approach that provides connectivities based on the NOE. The NOE is an alteration in signal intensity based on a direct through-space mechanism that is distance dependent, and thus the experiment can be used to probe internuclear distances. The 2D NMR NOE experiment is called NOESY and has the pulse sequence:

$$-\text{RD} - 90^\circ - t_1 - 90^\circ - t_m - 90^\circ - \text{ACQ}(t_2) -$$

In addition to the usual evolution time,  $t_1$ , this sequence contains a fixed mixing time  $t_m$  during which the NOE information is generated. The 2D NOESY spectrum consists of a diagonal, plus cross-peaks at the chemical shifts which demonstrate an NOE.

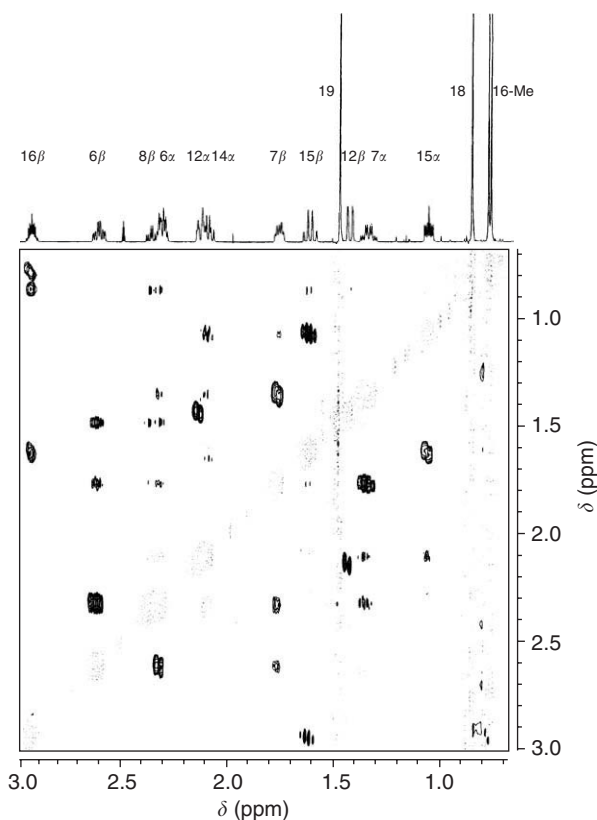

One of the problems with this experiment is that both chemical exchange and NOEs cause transfer of magnetization, and so any peaks involved in chemical exchange that is slow on the NMR timescale (i.e., those components that give rise to separate peaks) will also show cross-peaks in the 2D NOESY spectrum. On the other hand, this can be useful for studying complex exchanging systems. One way of partially separating NOE from chemical exchange cross-peaks is to carry out the experiment in phase-sensitive mode. In this mode chemical exchange effects give negative peaks and NOEs can give rise to both positive and negative peaks according to the tumbling rate of the molecule in solution and the Larmor frequency of the nuclei. The 2D NOESY

experiment is the major tool in the determination of the detailed 3D structure of proteins.

By varying the value of the mixing time  $t_m$ , it is possible to derive information on the rate at which the NOE builds up. This can give more detailed information on the internuclear distances.

The magnitude and sign of a proton–proton NOE is dependent on both the molecular tumbling rate and the NMR observation frequency. When using high-field NMR spectrometers, for molecules in the molecular mass range  $\sim 1000$  Da, NOEs can be close to zero, even if the nuclei are close together in space. One way of overcoming this limitation is to carry out a ROESY experiment, named because the NOEs are generated in the rotating frame. The pulse sequence is identical to the TOCSY sequence given earlier for connectivity via spin–spin coupling with the mixing time  $t_m$  now defined as the spin-lock period. This is usually applied for longer but at a lower power than for TOCSY studies. The distinction of NOE cross-peaks from other effects in ROESY spectra is not always easy, but complicating effects can sometimes be distinguished by the different peak phases that result.

Figure 3 shows the 600 MHz 2D ROESY NMR spectrum of dexamethasone. In this presentation, the

**Figure 3** Partial 600 MHz  $^1\text{H}$ – $^1\text{H}$  ROESY NMR spectrum of dexamethasone in  $\text{DMSO-d}_6$  acquired with a mixing time of 200 ms. The region from  $\delta 0.7$  to  $\delta 3.0$  is shown.

negative diagonal is shown with dotted contour lines and the positive cross-peaks are depicted with full line contours. A mixing time of 200 ms was used. Cross-peaks are observed at the chemical shifts of protons that experience a direct through-space dipolar interaction that is usually strongly distance dependent, thus indicating which hydrogens are close in space.

### Proton–Heteronuclear Chemical Shift Correlation

Correlation between  $^1\text{H}$  chemical shifts and heteronucleus chemical shifts such as  $^{13}\text{C}$  or  $^{15}\text{N}$  can be achieved through a number of 2D NMR experiments in which the heteronucleus is detected directly such as INEPT or DEPT. However, it is also possible to obtain the same type of correlation but with the advantage of the detection (i.e., the  $t_2$  dimension) at the much more sensitive  $^1\text{H}$  nucleus. This type of approach is called inverse detection. One problem is that  $^1\text{H}$  NMR signals from protons attached to the 99% of naturally abundant  $^{12}\text{C}$  nuclei have to be suppressed, leaving only the  $^1\text{H}$  signals from protons attached to the 1% of carbon nuclei which are  $^{13}\text{C}$  at natural abundance. This can be readily achieved, and if the pulse sequence also includes broadband heteronucleus decoupling (e.g., covering the  $^{13}\text{C}$  chemical shift range) then a 2D NMR presentation is possible in which each  $^1\text{H}$ – $^{13}\text{C}$  correlation peak appears as a singlet, the connectivity being based on  $^1\text{H}$ – $^{13}\text{C}$  spin coupling. This presentation, unlike the homonuclear correlation experiments, has no diagonal peak and the axes correspond to the appropriate chemical shift ranges of the  $^1\text{H}$  and  $^{13}\text{C}$  nuclei.

One main experimental approach is termed heteronuclear multiple quantum coherence, or HMQC, and the result is achieved by making use of the fact that coupled  $^1\text{H}$  and  $^{13}\text{C}$  nuclei can experience magnetization effects involving both spins, i.e., multiple quantum effects, which evolve during the evolution period  $t_1$ . The pulse sequence is given in Figure 4. An explanation of how this pulse sequence works is beyond the scope of this article but is available in standard texts. The scheme labeled BIRD is called a bilinear rotation decoupling sequence and has the effect, by optimizing the delay  $\tau$ , of removing  $^1\text{H}$  resonances of protons attached to  $^{12}\text{C}$  nuclei. The delay  $\Delta$  is set to the reciprocal of twice the one-bond  $^1\text{H}$ – $^{13}\text{C}$  spin coupling constant. To efficiently decouple all of the  $^{13}\text{C}$  nuclei from the protons, special pulsed decoupling schemes have been developed to cover the wide range of frequencies required (called WALTZ and GARP). Another related pulse sequence is termed heteronuclear single quantum coherence and this gives analogous information, but with better

**Figure 4** The NMR pulse sequence for the  $^1\text{H}$ -detected (inverse detection),  $^1\text{H}$ – $^{13}\text{C}$  correlation 2D NMR spectrum (HMQC). The initial part of the sequence, labeled BIRD, is a pulse scheme for removing from the spectrum the  $^1\text{H}$  resonances of protons attached to  $^{12}\text{C}$  nuclei. The filled symbols denote  $90^\circ$  pulses and the open symbols denote  $180^\circ$  pulses.  $x$ ,  $y$ , and  $\theta$  refer to RF pulse phases. The delay  $\Delta$  is set to  $1/(2 \times J_{\text{CH}})$ . GARP denotes a pulse method of spin decoupling all  $^{13}\text{C}$  nuclei.

**Figure 5** Partial 600 MHz  $^1\text{H}$ – $^{13}\text{C}$  HMQC NMR spectrum of dexamethasone in  $\text{DMSO-d}_6$  acquired using magnetic field gradients. Only the  $^1\text{H}$  region from  $\delta 0.7$  to  $\delta 3.0$  and the  $^{13}\text{C}$  region from 12 to 48 ppm are shown.

sensitivity. Analogous pulse sequences exist based on long-range  $^1\text{H}$ – $^{13}\text{C}$  couplings can then give connectivity information for quaternary carbons.

Figure 5 shows the 600 MHz  $^1\text{H}$ – $^{13}\text{C}$  HMQC spectrum of dexamethasone. Again an expansion of the spectrum is shown which corresponds to the earlier figures. In this case, the horizontal ( $\omega_2$ ) axis

represents the  $^1\text{H}$  NMR chemical shifts and the vertical ( $\omega_1$ ) axis corresponds to the  $^{13}\text{C}$  chemical shifts. A cross-peak is observed where the chemical shifts of directly bonded C–H nuclei intersect. It should be noted that where a  $\text{CH}_2$  group has two protons with different chemical shifts, then two peaks appear on the  $^1\text{H}$  axis at the same position on the  $^{13}\text{C}$  axis.

## Incorporation of Magnetic Field Gradients

Changing the phase of the RF pulses and of the receiver in an NMR experiment in a systematic fashion (phase cycling) has been the method used to select only signals of interest, to eliminate artifacts, and to achieve quadrature detection in the  $t_1$  dimension. However, often 4, 8, or even 16 steps are needed for every  $t_1$  increment in a 2D NMR pulse sequence in order to achieve the correct level of suppression of undesired peaks. If the sensitivity of the experiment is such that one scan for each  $t_1$  increment would have been sufficient, then significant time is wasted in the data acquisition.

A new alternative method has been introduced for achieving all of the above ends. This is accomplished using pulsed magnetic field gradients along the main magnetic field axis. At least two such gradients are inserted into a pulse sequence, the first to cause dephasing of transverse magnetization and the second, some time later, to refocus only the components of magnetization that are desired. This can all be done in one scan, so removing the need for multiple scans for each  $t_1$  increment. This results in much more efficient data acquisition. Some of the disadvantages of using gradients include the fact that the method is inherently less sensitive than phase cycling, plus any molecular diffusion process that occurs during the pulse sequence will cause loss of signal intensity if the timing and strength of the gradients are not considered carefully. Field gradients are now used routinely for selecting exactly which part of the magnetization is detected.

## Three-Dimensional NMR Spectroscopy

Extension to 3D NMR spectroscopy is achieved by inserting a further evolution and mixing period. This means that a third time axis is introduced. Thus, a 3D experiment can be considered as two tandem 2D experiments, and 3D NMR spectra can be visualized as contour peaks in a cube defined by three axes,  $\omega_1$ ,  $\omega_2$ , and  $\omega_3$  derived by three Fourier transformation steps from the three time axes  $t_1$ ,  $t_2$ , and  $t_3$  (the

acquisition time). One example would be a  $^1\text{H}$  NOESY–TOCSY spectrum where  $t_1$  is the NOESY evolution time and  $t_2$  is the TOCSY mixing time. In this case, the  $\omega_1$ – $\omega_2$  plane is equivalent to a 2D TOCSY spectrum, the  $\omega_2$ – $\omega_3$  plane is a 2D NOESY spectrum, and the  $\omega_1$ – $\omega_3$  plane, sometimes referred to as the back-transfer plane, contains peaks from spins that are correlated through both NOE and  $J$  coupling. The 3D display is viewed as a stack of 2D planes that are parallel to one of the axes, usually  $\omega_3$  since this normally has the highest digital resolution.

Following the characterization of the human genome sequence and the identification of specific proteins coded for by the genes, this has led to a resurgence of interest in protein structure determination, or structural genomics as it is sometimes called. There are a number of important 3D NMR experiments that are used for assigning the peaks in NMR spectra of macromolecules such as proteins, which have been obtained fully labeled with  $^{13}\text{C}$  and  $^{15}\text{N}$ . Additionally, 3D NMR spectroscopy has been used to investigate the structures of synthetic polymers.

### Introduction

As in nuclear magnetic resonance (NMR) of liquid samples, solid-state NMR probes the magnetic interactions of atomic nuclei. These interactions yield detailed information about the local structure and dynamics of the sample, including the bonding types and geometry, the site-site connectivity patterns, and the spatial characteristics and time scales of atomic and molecular motions. All kinds of solids can be studied with NMR, including single crystals and powders, disordered materials such as glass and rubber, and metals and superconductors. Spectral resolution, although not as high as in liquid-state NMR, is extraordinary (parts per million or better) but sensitivity is not. Sample volumes of order 50  $\mu\text{l}$  are typical.

The magnetic interactions probed in solid-state NMR include those studied in the liquid state, beginning with the Zeeman interaction between the nuclear spin and the applied magnetic field. This induces precession at the Larmor frequency  $\omega_0$ , which is defined by the nucleus and the strength of the external field. Fields as high as 21.2 T are in use, yielding proton Larmor frequencies of 900 MHz. Internal interactions observed include the chemical shift and, in favorable cases, scalar couplings. Additionally, magnetic dipole and electric quadrupole interactions, which are observable only indirectly in liquid-state NMR spectra, can be detected as frequency shifts in the solid state. In metals, the major spectral observable is the Knight shift. Because all these interactions depend sensitively on the local bonding geometry, they can be used to measure dynamic properties of the sample, either directly through spectral changes as a function of experimental parameters, or indirectly through the nuclear spin relaxation time.

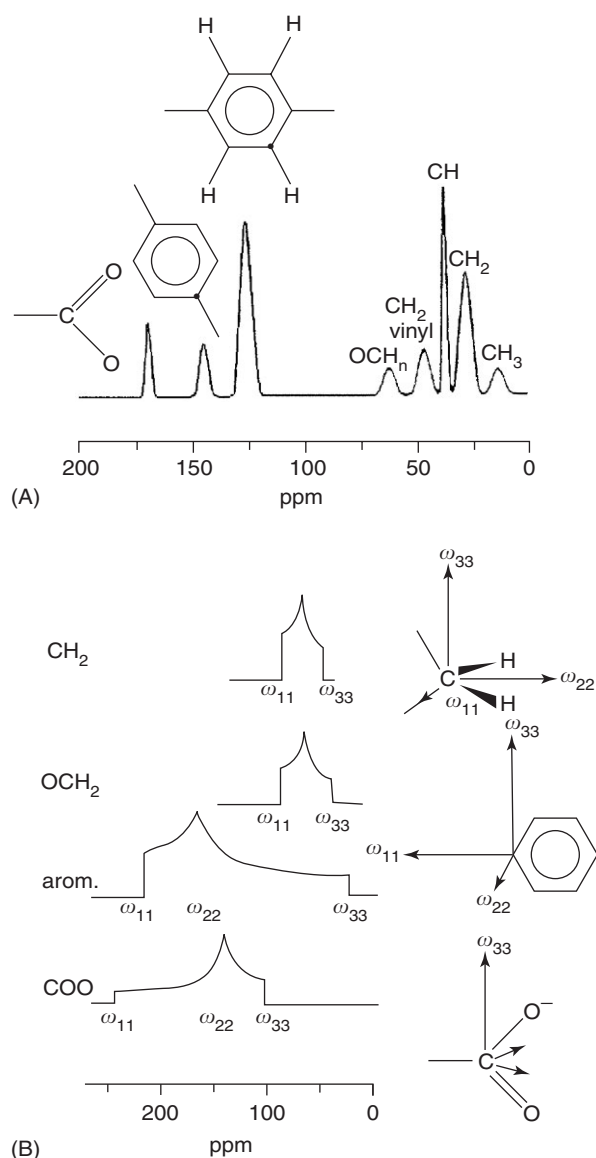

The primary difference between solid-state and liquid-state NMR is one of time scale. The atomic dynamics of the sample define a natural internal time scale, denoted  $\tau$ . The motion of interest might be, for example, the rotational tumbling of molecules in a liquid, the reorientation of segments in a polymer, or the hopping of ions in a solid electrolyte. Clearly,  $\tau$  can range from picoseconds to seconds or more. As

the observed nucleus moves to different locations or orientations, its NMR spectrum changes. This occurs both because the different sites may differ chemically, and also because the observable interactions are orientation dependent, the sense of orientation being defined by the external magnetic field. The different orientations define a range of frequencies  $\Delta\omega$  centered on the Larmor frequency. If  $\Delta\omega\tau \gg 1$ , a given nucleus samples many local environments during the NMR experiment. All interactions that depend on molecular orientation are in this way averaged to zero, and the spectrum is 'liquid-like'. 'Solid-like' spectra result when  $\Delta\omega\tau < 1$  for then the anisotropic portions of the interactions remain. These include for example the above-mentioned magnetic dipole and electric quadrupole terms. Typical examples of both regimes are shown in **Figure 1**.

**Figure 1** also shows the principal difficulty encountered in solid-state NMR spectra: the additional information provided by the anisotropic interactions can seriously congest the spectrum, making interpretation difficult. Our aim in this article is to outline the current principle methods by which solid-state NMR spectra can be acquired in interpretable form. Rather than giving an exhaustive account of the current developments in the field, we present the most important techniques in the context of the physical and chemical problems that they can help to solve.

### Resolving Chemically Distinct Sites

The most frequent application of solid-state NMR, as in the liquid state, is resolution of chemically distinct sites in a material. However, as **Figure 1** shows, the anisotropy observed in solid spectra typically creates so much spectral congestion that assignment is difficult. Moreover, as **Figure 1** also shows, the anisotropically broadened lines exhibit a variety of step and singularity features which, while informative in their own right, further obstruct a rapid assessment of the types and relative concentrations of distinct sites. The most important method for improving resolution in solid-state NMR is magic angle spinning (MAS). This method, so called because the sample is rotated about an axis inclined at the magic angle of  $54.74^\circ$  with respect to the magnetic field, can enhance the resolution by more than two orders of magnitude. It arises because the dominant anisotropies transform under rotations as second-rank spherical tensors, that is, like d-orbitals. Recall that the  $d_{22}$  orbital has an angular node; this is in fact at  $54.74^\circ$ . Thus, an interaction that transforms in the

**Figure 1** (A) Typical chemical shifts of carbon in different functional groups. The linewidths indicate the ranges observed; in a liquid sample, the actual linewidth will typically be much smaller. (B) Chemical shift powder patterns of carbons in the same functional groups. Such shapes are observed in powdered solids. The complex shapes, with steps and singularities, arise from the nontrivial orientation dependence of the chemical shift interaction, which is averaged to zero in a liquid but is observable in solids. The powder patterns are shown separately here for convenience; in real samples they overlap, making interpretation difficult. This problem is addressed by techniques such as magic angle spinning. (Reproduced with permission from Schmidt-Rohr K and Spiess HW (1994) *Multidimensional Solid-State NMR and Polymers*. London: Academic Press.)

same way can be averaged to zero by spinning about an axis located at this node.

To achieve effective averaging, the rotation frequency  $\omega_r$  in MAS must be of the order of, or greater than, the spread of interaction frequencies:

**Figure 2** The effect of magic angle spinning. The figure shows  $^{31}\text{P}$  spectra of  $\text{Na}_4\text{P}_2\text{O}_7 \cdot 10\text{H}_2\text{O}$ , as a function of rotor frequency. Note the extreme line-narrowing achieved, while still in a powdered solid. This illustrates that the symmetry of the chemical shift interaction is such that the full isotropic averaging of the liquid state is more than necessary to suppress the anisotropy; rotation about a single axis is in this case sufficient. The small splittings show that crystallographically, as well as magnetically, different sites can be resolved. (Adapted from Schnell I (1996) Diploma Thesis, Johannes-Gutenberg-Universität Mainz; see also and reproduced with permission from Kubo A and McDowell CA (1990) *Journal of Chemical Physics* 92: 715; © American Institute of Physics.)

$\omega_r/\Delta\omega > 1$ . The resulting resolution enhancement is dramatic, as shown in **Figure 2**.

For nuclei like  $^{13}\text{C}$ ,  $^{31}\text{P}$ , and  $^{29}\text{Si}$ , which have modest chemical shift ranges, spinning frequencies of 5–10 kHz are often sufficient, and are well within the range of typical commercial MAS probes.  $^1\text{H}$  spectroscopy is particularly challenging in solid-state NMR, in contrast to liquids, because of the strong magnetic dipole coupling between protons. This interaction gives a proton linewidth typically in the

range of 20–50 kHz. Commercial MAS NMR probes are now available with spinning frequencies above 35 kHz, and so in many cases even  $^1\text{H}$  solid-state NMR can be accomplished with the MAS technique.

While MAS can provide significant resolution enhancement, it enhances sensitivity only insofar as the signal from broad resonances is concentrated into narrower resonances. For naturally low-abundance nuclei like  $^{13}\text{C}$  (1% naturally occurring), this increase may be insufficient. For dilute spins in the presence of an abundant species with good sensitivity (such as protons), which is to say, nearly all organic solids, double resonance methods may be used to achieve an additional gain in sensitivity. Coupled with MAS, these techniques are collectively referred to as cross-polarization MAS (CP-MAS). In CP-MAS, magnetization is first excited using the abundant species (typically  $^1\text{H}$ ), and then transferred to the dilute species ( $^{13}\text{C}$  or  $^{15}\text{N}$ , say) by simultaneously irradiating both nuclei, at their respective Larmor frequencies. Then, the dilute spin is detected, often with decoupling of the abundant spin. All this is carried out in the presence of MAS, to obtain good resolution of the resulting spectrum. The theoretical sensitivity gain is the ratio of the Larmor frequencies of the two species, for example, 4 for the  $^1\text{H}$ – $^{13}\text{C}$  pair. In practice, protons often have significantly shorter relaxation times than their CP partners, so this method also allows for shorter recycle delays in pulsed NMR, and thus more rapid acquisition of the spectrum. A disadvantage of CP-MAS is that the CP efficiency is a function of proximity of the abundant and dilute species, so that CP-MAS spectra cannot be assumed to be quantitative reflections of the abundances of the resolved sites. This limits the use of CP-MAS-NMR for analytical applications.

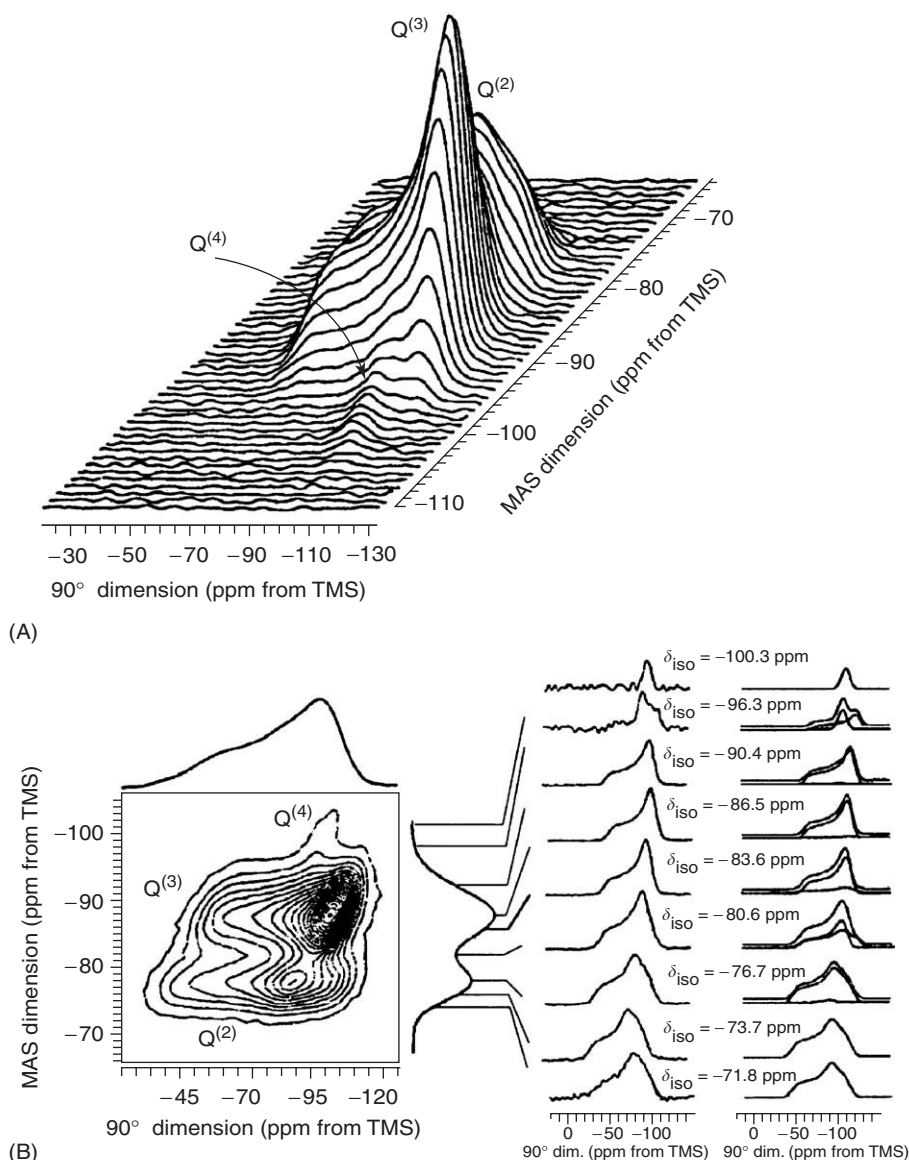

While MAS and CP-MAS are often sufficient to resolve chemical sites for nuclei like  $^{13}\text{C}$ ,  $^{31}\text{P}$ , and  $^{29}\text{Si}$ , this is not the case for other nuclei such as  $^{27}\text{Al}$ ,  $^{17}\text{O}$ , and  $^{11}\text{B}$ . The reason is that the first group of nuclei has spin 1/2, while the second have higher spin. Nuclei with spin greater than 1/2 are subject to electric quadrupole effects, in addition to the chemical shift, and these effects present a significant additional source of line broadening. Because the quadrupole anisotropy in the presence of a strong magnetic field does not transform simply like a second-rank tensor, it cannot be removed completely by MAS alone. During the last 15 years significant progress has been made in devising methods to average quadrupole interactions in addition to chemical shift anisotropy. In particular, multiple-quantum magic angle spinning (MQ-MAS) has become popular, which uses not just an MAS probe, but also a complex pulse sequence to excite and detect

triple- and higher-order coherences during the MAS experiment. As in CP-MAS, the technique is not analytically quantitative as uniform excitation of different chemical sites is difficult with existing pulse sequences. Despite such limitations impressive resolution advances for quadrupolar nuclei (**Figure 3**) have been achieved.

The methods described above yield greatly enhanced resolution, and as such help to determine the types and amounts of distinct sites in a material. This resolution gain comes at the price of discarding the information available from the interaction anisotropies. This information typically relates to the local site symmetry, for example, distortions in the bond angles, number of nearest neighbors, and so forth.

**Figure 3**  $^{87}\text{Rb}$  spectra of  $\text{RbNO}_3$ : (A) shows the static spectrum, while (B) shows the effect of magic angle spinning. The symmetry of strong quadrupole interactions is such that spinning about a single axis alone is not sufficient to remove all the anisotropy broadening. (C) Shows the results of multiple-quantum magic angle spinning, one of several methods currently available to obtain high-resolution spectra of quadrupolar nuclei like  $^{87}\text{Rb}$ . In this spectrum the three crystallographically distinct rubidium sites are resolved, and the total line narrowing is comparable to that achieved by MAS alone for spin-1/2 nuclei like  $^{13}\text{C}$  and  $^{31}\text{P}$  (see **Figure 2**). (Reproduced with permission from Brown S (1998) DPhil Thesis, Oxford University; and Brown SP and Wimperis S (1997) *Journal of Magnetic Resonance* 128: 42–61.)

**Figure 4** A separation of interactions-type spectrum of  $^{29}\text{Si}$  in a glass. (A) By spinning the sample off the magic angle during the first part of the experiment, and on the magic angle in the second, a two-dimensional spectrum is generated that has a high-resolution dimension correlated with the anisotropies of the individual sites. (B) Here, in a glass, each site itself shows a distribution of environments, which can be mapped out quantitatively by taking slices through the two-dimensional spectrum. In this way, for example, bond angle distributions, even in complex materials, can be determined, often with superior precision as compared to diffraction-based methods. (Reproduced with permission from Zhang P and Spiess HW (1996) *Journal of Non-Crystalline Solids* 204: 294.)

Both high-resolution and interaction anisotropies may be obtained by taking advantage of a second spectral dimension, using the so-called 'separation of interactions' experiments. An example is shown in **Figure 4**, where it is seen that the anisotropically broadened resonances are sorted according to their isotropic shift. In this way each resonance may be examined in isolation, and the anisotropy parameters determined with no congestion from neighboring bands. There are many ways to implement such experiments; an elegant approach for simple chemical shift correlations is to spin the sample at an angle

other than the magic angle during the first part of the experiment, followed by a hop to the magic angle and subsequent signal acquisition. In this way the anisotropic interactions 'label' the detected signal, and a double Fourier transform gives the type of spectrum shown in **Figure 4**.

### Determining the Connectivity between Sites

Once the types of sites in the material have been determined, using, for example, the techniques

discussed above, the second step in determining the material structure can be considered, namely, what the connectivity between these sites is. In liquid-state NMR, connectivities are primarily determined through scalar couplings, a through-bond interaction mediated by the electrons. However, this interaction is very small compared to the anisotropies of the magnetic interactions, and so is hard to probe in solids in any but well-ordered samples. On the other hand, magnetic dipole interactions, that is, the through-space effects of the nuclear magnetic moments on each other, can be substantial. This interaction varies with distance as  $r^{-3}$ , and so is of particular use in determining local structure. As noted above, dipole-dipole couplings are averaged to zero in 'liquid-like' spectra, but in solids they have easily observable effects on the resonance line shapes. Such interactions are also observed *indirectly* in liquids, through the nuclear Overhauser effect, where they appear as second-order interactions and thereby survive the averaging due to the molecular motion. Knowledge of the through-space connectivities does not give directly a map of the bonding network, but when combined with knowledge of the material composition and chemistry, can yield much about the bonding pattern.

For example, the CP-MAS experiment described above can already be used to obtain some degree of through-space information. The magnetization transfer, from  $^1\text{H}$  to  $^{13}\text{C}$  say, is mediated by the magnetic dipole interactions. By varying the duration of the transfer time (usually called the contact pulse) sites can be distinguished by their transfer efficiency. For example, primary and secondary carbons can be selectively excited, relative to tertiary and quaternary carbons, due to their greater proximity to protons. This is done simply by using a short contact pulse. Much more elaborate spectral editing schemes yield more accurate results, and are more flexible.

While variants of CP-MAS are particularly suitable for exploring proximities in heteronuclear systems with protons as one partner; other experiments can be performed to probe other heteronuclear systems and homonuclear couplings. All make use of the dipole-dipole coupling as the mechanism for encoding distance information.

In general, one wants to combine the distance measurement with some kind of resolution enhancement, in order to determine which sites are close to which. This is not always possible. For example, in many inhomogeneous solids, only one (broad) resonance will be observed, even with MAS or similar techniques. A well-studied example is sodium in a glass. Because techniques like MAS average the dipole-dipole coupling to zero, if they do not provide

sufficient resolution enhancement, they should not be used. Then, one studies a static sample. The spatial distribution of species in a static sample can be estimated by measuring the decay properties of spin echoes.

In spin echo experiments, an excitation pulse is followed at some time  $\tau$  later by a refocusing pulse. At time  $\tau$  after the second pulse, an echo will typically form. A classic use of this experiment for measuring distances is to estimate the so-called second moment ( $M_2$ ) of the resonance line. Interactions on a local scale, for example, the chemical shift and quadrupole interactions, and interactions involving isolated pairs of spins, can be refocused by using suitably chosen pulses. However, dipole coupling to a bath of partners cannot. Therefore, the echo cannot be refocused indefinitely, but only up to a characteristic time which is a measure of properties of the bath of nuclei coupled to the studied species. The decay constant of the spin-echo envelope is proportional to  $M_2$ , which is given essentially by summing over  $r_{ij}^{-6}$ , where the  $r_{ij}$  are internuclear distances. Because of the exponent  $-6$ , this experiment gives short-range information. It is valuable in assessing qualitative features of the distribution of species in inhomogeneous materials. An important extension of this experiment is called SEDOR, for spin-echo double resonance, in which an additional refocusing pulse is applied to a second nuclear species, and the echo signals with and without this secondary pulse are compared. In this way the mixing of different species in an inhomogeneous solid may be assessed.

Similar to SEDOR, but appropriate for isolated pairs of spins is the rotational echo double resonance method, or REDOR. In REDOR, the combined dynamics of the isolated two-spin system and the sample rotation serve to generate echoes at the rotor period. These echoes can be dephased by application of a pulse to one of the coupled partners. The amount of dephasing caused by this additional pulse is a measure of the coupling strength, and hence proximity, of the spins in the pair. This experiment is mostly applied to doubly or multiply labeled samples, for example, biopolymers enriched with  $^{13}\text{C}$  and  $^{15}\text{N}$ .

When the spectrum of the material consists of resolved resonances, much more detailed information on the nuclear distances can be derived than is possible with the spin-echo techniques outlined above. Magnetic dipole coupling is still the interaction to probe, but when the various sites are resolved, experiments can be used that give signals only if two distinct sites are near enough to each other to have a significant interaction. Clearly this yields much more detailed information than when the sites

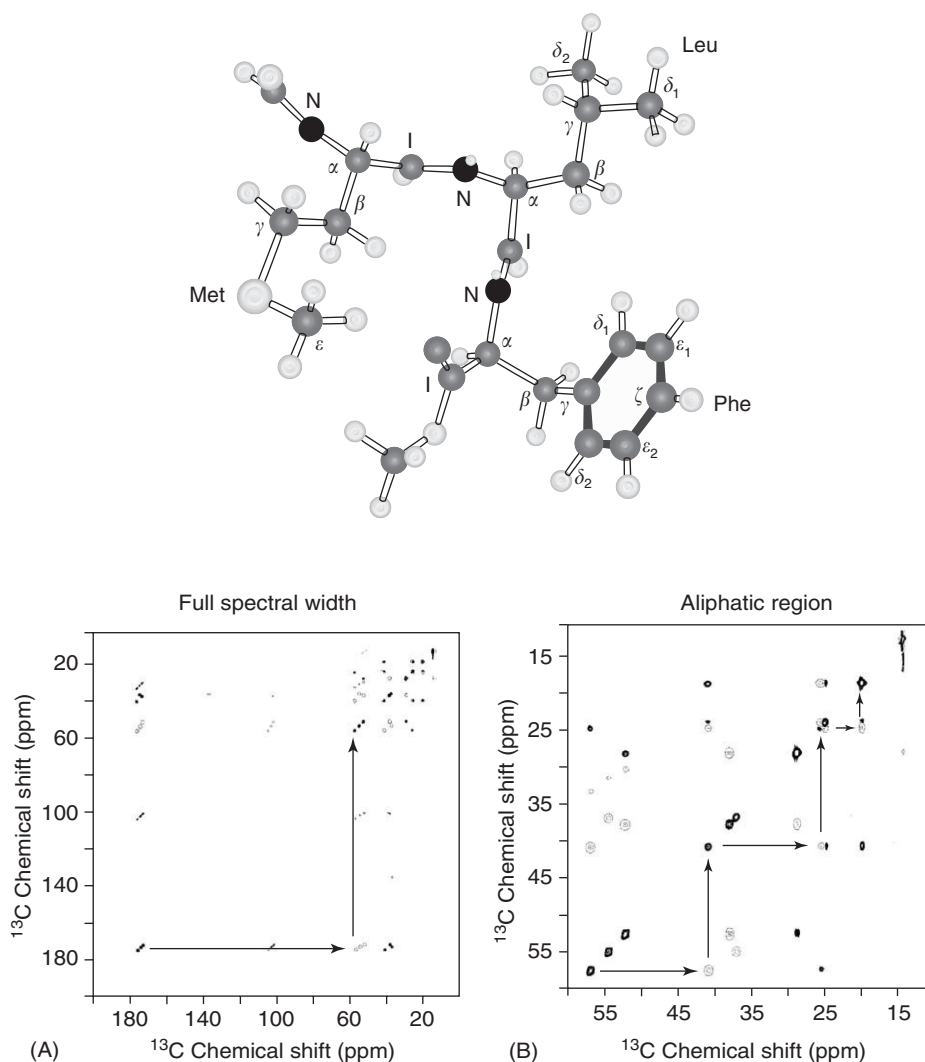

serve primarily to generate a background bath. Several types of signals can be generated and measured in this context, but the most precise are the so-called double quantum coherences. Isolated nuclei (here we have in mind only spin-1/2, such as  $^1\text{H}$  or  $^{13}\text{C}$ ) do not have enough energy levels to support quantum number changes greater than one, and therefore also cannot support coherences greater than one. If two such spins are coupled, however, the composite system can support two-quantum coherence. Experiments can be designed that are selective only for two-quantum coherence, thus yielding a connectivity map of the sites that are close enough spatially to couple in this way.

Generating such a connectivity map for a solid requires additionally a resolution-enhancement

technique, such as MAS. Such techniques, as discussed previously, suppress precisely the spin-spin interactions that the connectivity map is meant to reveal. Therefore, to combine multiple-quantum experiments with MAS, a pulse sequence that counteracts the averaging effect of MAS, thereby restoring the dipole-dipole coupling, must be implemented during excitation and evolution of the two-quantum coherence. A variety of such dipolar recoupling sequences currently exist, of varying levels of performance and complexity.

The resulting two-dimensional spectra give a connectivity map that can be traced in much the same way as is routinely done for liquid samples (Figure 5).

Such approaches are particularly important in biological applications to elucidate, e.g., the structure

**Figure 5** Double-quantum  $^{13}\text{C}$ – $^{13}\text{C}$  correlation spectra of the solid chemotactic tripeptide formyl-Met-Leu-Phe-OH. Such two-dimensional spectra give signals due to spatially proximal carbons, and thus provide means for determining the conformation of insoluble peptides. Together with other two- and three-dimensional experiments, solid-state NMR structures of proteins are now within reach, as is done routinely in liquid NMR using scalar couplings (a through-bond interaction). (Reproduced with permission from Rienstra C *et al.* (2000) *Journal of the American Chemical Society* 122: 10979–10990; © American Chemical Society.)

of membrane proteins, a rapidly developing field. It must be remembered, of course, that the signals observed reflect coupling through space, not through chemical bonds, so additional information about the chemistry must be used to interpret such spectra. Nevertheless, this method is fast becoming routine, as it requires only standard solids NMR instrumentation.

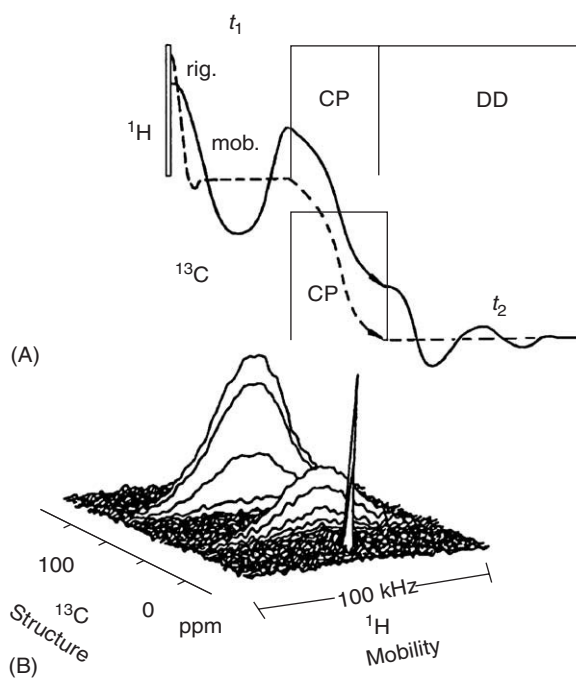

## Dynamics in Solids

The dynamics of atoms in solids may be probed directly, through their effects on the NMR spectra, and indirectly, through the nuclear spin relaxation. Because the NMR signal is observed only after the nuclear magnetization has been perturbed from its equilibrium state, relaxation is a standard feature of all NMR experiments. Two primary relaxation processes are usually identifiable. The first is the relaxation of the total magnetization back to its thermal equilibrium value; this occurs on a time scale denoted  $T_1$ . The second is the time scale for relaxation of quantum coherences in the spins, and is denoted  $T_2$ . In liquids, due to the strong decoupling resulting from the molecular motion, these two processes occur on similar time scales. In solids, however, they are usually very different, with  $T_2$  ranging typically from  $10^{-4}$  to  $10^{-2}$  s, and  $T_1$  from  $10^{-3}$  to  $10^{+3}$  s. Relaxation occurs because fluctuations in the surroundings of a spin induce transitions within the spin quantum states. Therefore, measurements of relaxation times are indirect probes of the dynamics in the solid. However, identifying what sort of fluctuation is operative is usually very difficult, unless one type of interaction is clearly dominant (conduction electrons in a metal or superconductor is a good example). Otherwise, the best that can be done is to estimate the temperature and magnetic field dependence of the relaxation to be expected from candidate fluctuation modes, and to compare the predictions with the data.

An easier qualitative assessment of dynamics can often be obtained from resonance line-shapes. As noted above, the key distinction between solid-like and liquid-like NMR spectra is the time scale of the atomic motions, compared to the frequency spread of the detected interactions. As the rate of a dynamical process increases, say as a function of temperature, it can be followed through changes in the linewidths of the nuclei involved. These changes can be substantial, as a resonance goes from solid-like at low temperatures to liquid-like at high temperatures, with the linewidth decreasing by orders of magnitude.

The linewidth strategy is particularly effective if no additional line narrowing is needed to interpret the low-temperature spectra; however, it is often the case

that these spectra will be so congested that additional techniques such as MAS must be applied. Then the line narrowing upon heating is much less dramatic. In this case, two-dimensional spectroscopy can again be very helpful. For organic solids and polymers the wideline separation of interactions (WISE) experiment is a convenient qualitative measure of the relative site dynamics. This experiment combines the good resolution found in  $^{13}\text{C}$  spectra under MAS, with the strong internuclear coupling of protons. The latter feature makes proton spectra particularly good indicators of motional narrowing due to dynamics: broad proton resonances (30–50 kHz) are seen in static samples, and narrow (<1 kHz) for mobile sites. The WISE experiment works by adding an additional evolution time to the CP-MAS sequence, between the proton excitation and the contact pulse

**Figure 6** Two-dimensional wideline separation of interactions spectrum of polystyrene–poly(dimethyl siloxane) di-block co-polymer (PS-*b*-PDMS). In the first part of the experiment (A) proton magnetization is allowed to evolve, and then transferred to carbon in the second part of the experiment. In this way the proton spectra of individual carbon sites are sorted by the shift of each site, and the result is a wideline proton spectrum in one dimension, and a high-resolution, MAS carbon spectrum in the other. In this example (B) the PDMS is seen to be quite mobile: it gives the carbon signal near 0 ppm, and the proton spectrum for this site is very sharp, indicating significant motional narrowing. The PS peaks, on the other hand, give very broad proton resonances, showing that the PS part of this block copolymer is essentially static at this temperature. With this experiment, quick qualitative assessments of relative local mobility in organic solids and polymers can be made. (Reproduced with permission from Schmidt-Rohr K and Spiess HW (1994) *Multidimensional Solid-State NMR and Polymers*. London: Academic Press.)

**Figure 7** Two-dimensional  $^2\text{H}$  exchange spectrum of deuterated dimethylsulfoxide. The strong diagonal ridge reflects molecules that have not reoriented during the mixing time, while the pattern of ellipses off the diagonal shows those that have. The ellipses arise due to the orientational dependence of the  $^2\text{H}$  quadrupole interaction, the dominant anisotropy here. The distribution of jump angles is shown on the right, and sharply peaked at zero (static molecules) and  $72^\circ$ , the included angle of the C–D bonds as the entire molecule executes hops about its symmetry axis. With this type of experiment, slow to moderate dynamics of molecules and polymers can be followed in atomic level detail. (Reproduced with permission from Schmidt-Rohr K and Spiess HW (1994) *Multidimensional Solid-State NMR and Polymers*. London: Academic Press.)

to the carbons, and using relatively slow sample spinning. In this way a two-dimensional spectrum is obtained, with proton resonances sorted by the carbon sites to which they are bonded (Figure 6).

One can immediately see, therefore, which carbon sites are mobile (narrow associated proton resonances) and which are static (broad proton resonances).

More detailed information on dynamics is available from the so-called exchange experiments. This class of two-dimensional techniques provides a correlation between spectral components, which exchange during a mixing period. The exchange may occur because of a chemical transformation during the mixing time, resulting in a new frequency due to a new chemical environment, or because of site re-orientation. Since the nuclear spin interactions are orientation dependent, if the molecular unit changes its orientation during the mixing time, the involved nuclear spins will exhibit altered NMR frequencies that can be correlated to their initial values. Because the orientation dependences of NMR interactions are well known, it is often a straightforward matter to relate the observed correlation spectrum to the underlying molecular motion that gave rise to it. In this way very detailed information on microscopic molecular dynamics can be obtained.

Deuteron NMR spectra provide particularly clear examples of the above approach. For deuterons ( $^2\text{H}$ ), the quadrupole interaction is by far dominant, and in a C–D bond is aligned with the C–D bond itself. Therefore, changes in time of the  $^2\text{H}$  quadrupole

orientation give a direct reflection of the orientational dynamics of the C–D bond itself. Figure 7 shows the  $^2\text{H}$  two-dimensional exchange spectrum of deuterated dimethylsulfone ( $(\text{CD}_3)_2\text{SO}_2$ ).

The strong diagonal ridge is a typical  $^2\text{H}$  NMR spectrum, and arises from molecules that did not exchange during the mixing time. The pattern of ellipses off the diagonal arises due to  $^2\text{H}$  nuclei with one orientation, and hence one frequency, at the start of the experiment, and a second orientation, hence frequency, after the mixing time. This pattern is consistent with  $180^\circ$  jumps of the molecules about their symmetry axis. The exchange experiment can be applied to other nuclei as well, such as  $^{13}\text{C}$ , although it can be harder to relate the spin interaction orientation to a molecular frame of reference.

### Introduction

Nuclear magnetic resonance (NMR) spectroscopy can be used as a powerful noninvasive tool for clinical and other investigations of tissue biochemistry *in vivo*. There are many techniques for obtaining spectra from only a localized region of tissue, the simplest being to use a surface coil probe as both radio-frequency (RF) transmitter and receiver. This article reviews briefly surface coil spectroscopy, covering design, spectroscopic techniques, and clinical applications.

*In vivo* NMR spectroscopy has enabled the investigation and monitoring of metabolic changes in living tissues *in situ*. Unlike many other biochemical techniques, it is noninvasive, facilitating studies on previously inaccessible tissues such as the brain.

Surface coils can provide superior signal-to-noise ratios (SNRs) compared with volume coils. They provide some degree of spatial localization because as RF transmitters they excite magnetization in only a relatively small volume of the subject, while as RF receivers they only detect signals from a similar volume. However, the sensitive volume is poorly defined – in order to acquire data only from the tissue of interest, careful attention must be paid to contaminating signals. Further techniques, using magnetic field gradients, can give a second degree of localization, but this article focuses primarily on using the surface coil alone.

*In vivo* spectra often contain many overlapping resonances, due to both the relatively poor static magnetic field ( $B_0$ ) homogeneity and the vast number of metabolites in biological systems; hence, peak overlap can present serious problems for interpretation of results. This effect is more severe at low field strengths (e.g., 2.4 T, see **Figure 1A**) but can still be significant at e.g., 7.0 T (see **Figure 1B**).

Phosphorus ( $^{31}\text{P}$ ) surface coil spectroscopy has produced fruitful results in clinical applications. This nucleus acts as a probe of energy metabolism, via phosphocreatine (PCr), inorganic phosphate (Pi) and adenosine triphosphate (ATP). It also allows monitoring of intracellular pH ( $\text{pH}_i$ ), using the Pi chemical shift, and membrane metabolism, via phosphomonoesters (PMEs) and phosphodiesteres (PDEs). Carbon ( $^{13}\text{C}$ ) spectroscopy is also a powerful probe of energy metabolism; however, in many cases the low natural abundance of this isotope and its poor intrinsic NMR sensitivity make it difficult to obtain adequate signal except by infusion of  $^{13}\text{C}$ -labeled compounds. It is harder to apply proton ( $^1\text{H}$ ) surface coil spectroscopy *in vivo*, both because of strong, contaminating signals from superficial tissues (e.g., subcutaneous fat) and because extremely good  $B_0$  homogeneity is needed since numerous  $^1\text{H}$  resonances appear within a narrow bandwidth. However,  $^1\text{H}$  surface coil spectroscopy has been applied successfully to *in vivo* studies of human and other mammalian brains (see **Figure 2**). Recent  $^1\text{H}$  studies usually combine surface coil localization with gradient-localized pulse sequences.

### Theory

A surface coil consists of one or more coplanar loops of conductor, capacitively tuned to the NMR RF of the nucleus of interest and impedance-matched to the spectrometer's receiver. The surface coil is positioned flatly against the body surface adjacent to the tissue under investigation. Both the RF magnetic field ( $B_1$ ) generated during pulse transmission and the spatial sensitivity during reception are highly inhomogeneous. Magnetization close to the coil windings experiences a greater flip angle during transmission and induces a larger signal during reception. Indeed, the well-known 'principle of reciprocity' states that, for each point in space, the detection sensitivity is directly proportional to the magnetic field generated by the same coil (per unit current) when used as a transmitter.

### Introduction

Nuclear magnetic resonance (NMR) spectroscopy can be used as a powerful noninvasive tool for clinical and other investigations of tissue biochemistry *in vivo*. There are many techniques for obtaining spectra from only a localized region of tissue, the simplest being to use a surface coil probe as both radio-frequency (RF) transmitter and receiver. This article reviews briefly surface coil spectroscopy, covering design, spectroscopic techniques, and clinical applications.

*In vivo* NMR spectroscopy has enabled the investigation and monitoring of metabolic changes in living tissues *in situ*. Unlike many other biochemical techniques, it is noninvasive, facilitating studies on previously inaccessible tissues such as the brain.

Surface coils can provide superior signal-to-noise ratios (SNRs) compared with volume coils. They provide some degree of spatial localization because as RF transmitters they excite magnetization in only a relatively small volume of the subject, while as RF receivers they only detect signals from a similar volume. However, the sensitive volume is poorly defined – in order to acquire data only from the tissue of interest, careful attention must be paid to contaminating signals. Further techniques, using magnetic field gradients, can give a second degree of localization, but this article focuses primarily on using the surface coil alone.

*In vivo* spectra often contain many overlapping resonances, due to both the relatively poor static magnetic field ( $B_0$ ) homogeneity and the vast number of metabolites in biological systems; hence, peak overlap can present serious problems for interpretation of results. This effect is more severe at low field strengths (e.g., 2.4 T, see **Figure 1A**) but can still be significant at e.g., 7.0 T (see **Figure 1B**).

Phosphorus ( $^{31}\text{P}$ ) surface coil spectroscopy has produced fruitful results in clinical applications. This nucleus acts as a probe of energy metabolism, via phosphocreatine (PCr), inorganic phosphate (Pi) and adenosine triphosphate (ATP). It also allows monitoring of intracellular pH ( $\text{pH}_i$ ), using the Pi chemical shift, and membrane metabolism, via phosphomonoesters (PMEs) and phosphodiesteres (PDEs). Carbon ( $^{13}\text{C}$ ) spectroscopy is also a powerful probe of energy metabolism; however, in many cases the low natural abundance of this isotope and its poor intrinsic NMR sensitivity make it difficult to obtain adequate signal except by infusion of  $^{13}\text{C}$ -labeled compounds. It is harder to apply proton ( $^1\text{H}$ ) surface coil spectroscopy *in vivo*, both because of strong, contaminating signals from superficial tissues (e.g., subcutaneous fat) and because extremely good  $B_0$  homogeneity is needed since numerous  $^1\text{H}$  resonances appear within a narrow bandwidth. However,  $^1\text{H}$  surface coil spectroscopy has been applied successfully to *in vivo* studies of human and other mammalian brains (see **Figure 2**). Recent  $^1\text{H}$  studies usually combine surface coil localization with gradient-localized pulse sequences.

### Theory

A surface coil consists of one or more coplanar loops of conductor, capacitively tuned to the NMR RF of the nucleus of interest and impedance-matched to the spectrometer's receiver. The surface coil is positioned flatly against the body surface adjacent to the tissue under investigation. Both the RF magnetic field ( $B_1$ ) generated during pulse transmission and the spatial sensitivity during reception are highly inhomogeneous. Magnetization close to the coil windings experiences a greater flip angle during transmission and induces a larger signal during reception. Indeed, the well-known 'principle of reciprocity' states that, for each point in space, the detection sensitivity is directly proportional to the magnetic field generated by the same coil (per unit current) when used as a transmitter.

**Figure 1**  $^{31}\text{P}$  surface coil spectra acquired noninvasively from mammalian brain *in vivo* at field strengths of (A) 2.4 T (40.6 MHz) and (B) 7.0 T (121.6 MHz). The 7.0 T spectrum (B) shows much greater resolution. (A) From the temporo-parietal cortex of a normal newborn human infant. Acquisition conditions: 6 cm single-turn coil;  $90^\circ$  flip angle at coil center;  $T_R = 2.256$  s; 256 summed free induction decays. Peak assignments: 1, PME (mainly phosphoethanolamine); 2, Pi; 3, PDE (mainly cross-linked PDEs); 4, PCr; 5–7,  $\gamma$ -,  $\alpha$ -, and  $\beta$ -NTP, respectively. The dashed line is a simulated spectrum generated from Lorentzian peaks, fitted by  $\chi^2$  minimization. The NTP peaks were fitted as doublets ( $\gamma$  and  $\alpha$ ) and a triplet ( $\beta$ ) with J-couplings of 16 Hz. (B) From normal neonatal porcine brain. Acquisition conditions: 2.5 cm two-turn, balanced-matched (inductively coupled), series-tuned coil;  $180^\circ$  flip angle at coil center;  $T_R = 10$  s; 384 free induction decays averaged. A DANTE pulse sequence (500 ten microsecond pulses, 200  $\mu\text{s}$  repetition time) was used prior to the acquisition pulse in order to reduce the broad bone and phospholipid signal. Additional resonance assignments: 8,  $\text{Pi}_1$  (probably extracellular and mitochondrial); 9,  $\text{Pi}_2$  (probably intracellular cytosolic); 10, glycerolphosphorylethanolamine; 11, glycerolphosphorylcholine; 12, nicotinamide dinucleotides. The simulated spectrum (dashed) was fitted in the manner described for spectrum (A). At 7 T the enhanced spectral resolution enables detection of additional resonances. Pi is resolved into two components (peaks 8 and 9), and, whereas the broad PDE signal (peak 3) is almost undetectable at 7 T (because of the effects of chemical shift anisotropy), two narrow resonances from mobile PDEs (peaks 10 and 11) are seen. Furthermore, nicotinamide dinucleotide is now clearly resolved from the adjacent  $\alpha$ -NTP doublet.

For any surface coil design, we can calculate  $B_1$  at any point in space by integrating the Biot–Savart law around the coil. For a single loop, planar surface coil of radius  $r_c$  in the  $y$ - $z$  plane of an orthogonal frame

**Figure 2**  $^1\text{H}$  surface coil spin-echo spectra obtained at 7.0 T (300 MHz) from *in situ* neonatal porcine brain post mortem. Data were collected using an EXORCYCLED  $1\bar{1}2 - \tau - 2 - \tau$ -acquire echo sequence with  $\tau = 66$  ms (a) and  $\tau = 135$  ms (b). The Hore  $1\bar{1}2$  and  $1\bar{1}2$  binomial solvent suppression sequences were used to reduce the signal from brain water. The  $1\bar{1}2$  and  $2\bar{2}$  interpulse delay was set to maximize the sensitivity for NAA  $\text{CH}_3$ - at  $\sim 2.02$  ppm. Acquisition conditions: coil as for **Figure 1B**;  $T_R = 1$  s; 256 summed echoes. Major resonance assignments: 1, lactate ( $\text{H}_\alpha$ ); 2, myo-inositol ( $\text{H}_2$ ); 3, creatine ( $\text{H}_\alpha\text{H}_\alpha'$ ); 4–6, glutamate and glutamine ( $\text{H}_\alpha$ ) and myo-inositol ( $\text{H}_4$  and  $\text{H}_6$ ); 7, glycine ( $\text{H}_\alpha$ ) and myo-inositol ( $\text{H}_1$  and  $\text{H}_3$ ); 8, taurine ( $\text{H}_\beta\text{H}_\beta'$ ); 9, phosphorylcholine and glycerolphosphorylcholine ( $-(\text{CH}_3)_3$ ) and taurine ( $\text{H}_\alpha\text{H}_\alpha'$ ); 10, creatine ( $\text{CH}_3$ -); 11 and 12, NAA ( $\text{H}_\beta$ ) and aspartate ( $\text{H}_\beta$  and  $\text{H}_\beta'$ ); 13 and 14, glutamate and glutamine ( $\text{H}_\gamma\text{H}_\gamma'$ ), NAA ( $\text{H}_\beta'$ ), and  $\gamma$ -aminobutyrate (GABA) ( $\text{H}_\alpha\text{H}_\alpha'$ ); 15, NAA ( $\text{CH}_3$ -) and small contributions from *N*-acetylaspartylglutamate ( $\text{CH}_3$ -), glutamate and glutamine ( $\text{H}_\beta\text{H}_\beta'$ ), and GABA ( $\text{H}_\beta\text{H}_\beta'$ ); 16, lactate ( $\text{CH}_3$ -); and 17, alanine ( $\text{CH}_3$ -). Residual unsuppressed water signals are seen at  $\sim 4.8$  ppm.

of reference  $xyz$  (see **Figure 3**), the radial ( $r$ ) and axial ( $x$ ) components of the  $B_1$  field at  $P(x, y, z)$  generated by the flow of unit current are given by

$$B_r = \frac{\mu_0}{2\pi} \frac{x}{\rho[(r_c + \rho)^2 + x^2]^{1/2}} \times \left[ -K(k^2) + \frac{r_c^2 + \rho^2 + x^2}{(r_c - \rho)^2 + x^2} E(k^2) \right] \quad [1]$$

$$B_x = \frac{\mu_0}{2\pi} \frac{1}{\rho[(r_c + \rho)^2 + x^2]^{1/2}} \times \left[ K(k^2) + \frac{r_c^2 + \rho^2 + x^2}{(r_c - \rho)^2 + x^2} E(k^2) \right] \quad [2]$$

where  $\mu_0$  is the permeability of free space, the off-axis distance of  $P$  is  $\rho = (y^2 + z^2)^{1/2}$ ,  $k^2 = 4r_c\rho/((r_c + \rho)^2 + x^2)$ , and  $E(k^2)$  and  $K(k^2)$  are complete elliptical integrals of the first and second kind, respectively. If points on the  $x$ -axis only are considered ( $y = 0, z = 0$ , and so  $\rho = 0, k^2 = 0$ ), both  $E(0)$  and  $K(0) = \pi/2$ , and

eqn [2] reduces to

$$B_x = \frac{\mu_0}{2} \frac{r_c^2}{(r_c^2 + x^2)^{3/2}} \quad [3]$$

Because NMR signals are weak, it may be desirable to use a pulse-sequence repetition time ( $T_R$ ) much less than five times the longitudinal relaxation time ( $T_1$ ) in order to maximize the SNR per unit acquisition time. The strong spatial dependence of the flip angle also causes the relaxation state of the nuclei to vary strongly with position. **Figure 4** shows the spatial sensitivity of a surface coil for various  $T_{RS}$ , demonstrating the imprecise boundary of the sensitive volume.

## Instrumentation

The specific requirements of many studies often require dedicated surface coils, and so it is useful to be able construct one's own.

### Surface Coil Design

A surface coil is a resonant circuit, with an inductive part (the conducting loops) and tuning capacitors. The simplest design (see **Figure 5**) consists of one or more loops of conductor (e.g., high-purity copper wire) tuned with a parallel-mounted, high-efficiency 'fixed' tuning capacitor ( $C_f$ ). A high-efficiency variable capacitor ( $C_t$ ) in parallel with this enables fine-tuning of the resonant frequency. The coil is coupled to the spectrometer by a further variable capacitance ( $C_m$ ) that matches the coil impedance to that of the spectrometer (usually  $50 \Omega$ ). The inductance,  $L_c$ , is given by

$$L_c = r_c n^2 \{ \mu_0 [\ln(8r_c/r_w) - 2] \mu' / 4 \} \quad [4]$$

**Figure 3** The radial ( $r$ ) and axial ( $x$ )  $B_1$  components at the point  $P(x, y, z)$ , generated by a unit current flowing in a single-turn surface coil.  $\alpha$  is the angle between  $B_r$  and  $B_0$ . (Reproduced with permission from Cady EB (1990). *Clinical Magnetic Resonance Spectroscopy*. New York: Plenum; © Plenum.)

**Figure 4** Signal amplitude maps in the  $x$ - $y$  plane, at  $z = 0$ , calculated for a single pulse under steady-state conditions with various  $T_{RS}$ . (A) Slow pulse repetition ( $T_R/T_1 = 5$ ). (B)  $T_R = T_1$ . (C) Rapid pulsing ( $T_R/T_1 = 0.05$ ). The signal amplitudes are normalized to 100 for a single  $90^\circ$  pulse at the coil center. (Reprinted with permission from Evelhoch JL, Crowley MG, and Ackerman JJH (1984) Signal-to-noise optimization and observed volume localization with circular surface coils. *Journal of Magnetic Resonance* 56: 110–124; © Elsevier.

**Figure 5** A circuit for a surface coil tuned for a single nucleus (e.g.,  $^{31}\text{P}$ ) with an add-on circuit that improves the efficiency at the  $^1\text{H}$  frequency (e.g., for shimming). The surface coil circuit (right-hand side) comprises the coil inductance,  $L_c$ , a fixed tuning capacitor,  $C_t$ , a variable tuning capacitor,  $C_t$ , and a variable matching capacitor,  $C_m$ . The add-on circuit (left-hand side) consists of a balanced length (approximately a quarter wavelength at the  $^1\text{H}$  frequency) of coaxial cable,  $d$ , and additional variable capacitors,  $C_1$  and  $C_2$ . (Reproduced with permission from Cady EB (1990). *Magnetic Resonance Spectroscopy*. New York: Plenum; © Plenum.)

where  $n$  is the number of turns of conductor,  $r_w$  is the radius of the wire, and  $\mu'$  is the conductor permeability. The required tuning capacitance ( $C_{\text{tune}}$ ) is given by

$$C_{\text{tune}} = \frac{1}{4\pi^2\nu^2 L_c} \quad [5]$$

where  $\nu$  is the resonant frequency in hertz. For a coil with this simple design, the duration,  $\tau$ , of the rectangular (hard) RF pulse required to produce a flip angle  $\theta$  on the  $x$ -axis is given by

$$\tau = \frac{40ZC_m r_c (r_c^2 + x^2)^{3/2}}{CV_t \gamma \mu_0 n r_c^3} \quad [6]$$

where  $Z$  is the spectrometer impedance,  $C$  is the total capacitance (i.e.,  $C_m + C_t + C_f$ ),  $V_t$  is the peak-to-peak transmitter voltage, and  $\gamma$  is the gyromagnetic ratio of the nucleus concerned.

When designing a surface coil, it is important to consider the study to be undertaken. The size of coil should match the sample dimensions as most spectroscopic information will be obtained from depths within about one coil radius. For too small a diameter, superficial tissues (i.e., skin and fat) occupy most of the sensitive volume, while for too large a diameter, other deeper or surrounding tissues may contribute a significant contaminating signal. Typical surface coil diameters are 3–10 cm for many human studies, or e.g. 1–2 cm for studying the brain of a small mammal. When the target tissue is skin, still smaller coils may be used or unusual coil geometries (such as the ‘crossover coil’ or the ‘zig-zag coil’) that detect strong superficial signals while having greatly reduced sensitivity further from the coil.

**Figure 6** (A) A series-tuned, balanced-matched, inductively coupled sample (primary) coil. This example consists of a single loop of conductor with two symmetrically positioned fixed tuning capacitors,  $2C_t$ , and a variable capacitor,  $C_t$ , for fine adjustment of the resonance frequency. The series tuning capacitors lower the coil voltage and should reduce dielectric losses. A secondary (impedance-matching) coil is required for coupling the primary to the spectrometer. (B) A circuit for a balanced-matched, inductively coupled surface coil.  $L_s$  is the inductance of the sample (primary) coil, which is tuned by  $C_t$  and  $C_t$ .  $L_m$  is the inductance of the matching (secondary) coil. The impedance matching can be fine-adjusted using  $C_m$ . (Reproduced with permission from Cady EB (1990). *Magnetic Resonance Spectroscopy*. New York: Plenum; © Plenum.)

It is important to position the tuning capacitances as close to the loops of the conductor as possible, minimizing unwanted inductances and capacitances – the ‘fixed’ capacitors should be almost integral components of the coil (see Figure 6A). Because the capacitances are quite close to the sample, they must be completely nonmagnetic; otherwise the  $B_0$  homogeneity will be compromised significantly. The coil components must be capable of handling the RF power to be used.

The optimum number of coil loops is usually  $<3$  and depends on the coil diameter and the NMR frequency of the nucleus concerned. Equation [5] implies that in order to tune the coil; the higher the frequency, the smaller the inductance (and hence the number of turns) or the capacitance. It is usually best to use the maximum number of turns compatible with tuning the coil to minimize the effects of stray inductances. The coil turns should be separated by a distance of  $\sim r_w$  to reduce interloop inductive effects. The loops must be insulated from each other and from the sample, both to ensure subject safety and to prevent coil earthing.

For good spectral quality, the coil's SNR should be optimized. As suggested by the principle of reciprocity, SNR losses as a receiver are closely related to energy losses as a transmitter. Both are quantified in terms of the surface-coil  $Q$ -factor, the proportion of energy lost per cycle. There are three sources of loss – the coil, the sample, and radiation losses. Coil losses result from both resistance and capacitor dielectric losses. Sample losses (loading) result from currents induced in an electrically conductive subject. Radiative losses refer to electromagnetic energy leaving the system.

Resistive losses in the coil are usually small compared with sample (loading) effects. However, at very low field strengths or for very small samples, resistive effects can dominate over other loss mechanisms. They can be reduced by exercising care in designing the coil geometry, by cooling the coil wires, or by making the coil from a high-temperature superconductor such as YBaCuO.

Dielectric losses in the capacitors may be more substantial, especially in heavily loaded coils where large transmitter voltages are needed. To reduce dielectric losses, various design improvements have been suggested that lower coil voltages. **Figure 6** shows one such design, known as a 'balanced-matched' coil. This probe consists of two coils forming an air-cored RF transformer: a primary coil (the sample coil that is positioned adjacent to the tissue of interest); and a secondary coil (used to impedance-match and couple the sample coil to the spectrometer). The mutual inductance is adjusted to match the primary coil impedance to that of the spectrometer, by fine-tuning either the physical position or a capacitance in series with the secondary coil. Dielectric losses are reduced in this design because voltages are distributed symmetrically about the tuning capacitances and therefore are smaller. In the example in **Figure 6**, the primary coil voltages are reduced still further using two tuning capacitances in series with the inductance (also split into two equal parts).

When a conductive sample (e.g., part of the human body) is brought near the probe, energy is dissipated by currents induced in the sample, thereby reducing the coil's efficiency. This effect, known as 'loading', increases with the RF, the sensitive volume of the coil, and the conductivity of the subject. *In vivo* loading nearly always dominates over other losses, most of which are reduced by good coil design. *In vivo* loading leads to a large reduction in  $Q$ . One consequence of this is the so-called 'lift-off effect' – a higher SNR may sometimes be achieved by displacing the coil a small distance from the subject because the reduced loading outweighs the drop in sensitivity due to increased distance.

Radiative losses are usually minimized by ensuring that all winding lengths are substantially less than the wavelength, and may be reduced further using radiation shields. Innovative designs such as 'microstrip' coils can also reduce radiative losses by combining the function of a shield with that of a distributed capacitance.

In addition to the nucleus of interest (e.g.,  $^{31}\text{P}$ ), the surface coil may need to detect the  $^1\text{H}$  signal from tissue water for sample shimming (making  $B_0$  uniform throughout the sample). Even for a coil tuned to  $^{31}\text{P}$ , a sufficient water signal may normally be detected, and its amplitude can be further increased by adding an extra tune-and-match network and a selected length of coaxial cable in series (see the left-hand side of **Figure 5**). Alternatively, a double-tuned coil may be used (see later) that may also be used for spectroscopy with the second nucleus.

Quadrature surface coils can improve the SNR by a factor up to  $\sqrt{2}$ . These consist of two separate coils that produce approximately mutually orthogonal  $B_1$  fields, with similar amplitudes, over much of the sensitive region (**Figure 7**). This allows the two circular polarizations to be distinguished. However, for a quadrature coil pair to function, there must be minimal coupling between the component coils – no net magnetic flux should be captured in one coil that originates from the other. One common design is to use two partially overlapping coils; ideally they will be tilted at  $90^\circ$ , but in practice the sample geometry usually requires a smaller angle. Another common design is a single loop overlapping a figure-of-eight double loop (butterfly) configuration, wrapped around a half circle.

In many applications, multinuclear coils are necessary, so that data may be acquired from more than one nucleus in the same experiment (e.g., both  $^1\text{H}$  and  $^{31}\text{P}$ ). The simplest design, allowing only sequential study of the different nuclei, changes the tuning capacitance, using a nonmagnetic microswitch to add a further capacitor in parallel to  $C_f$ . In more

**Figure 7** Two designs for quadrature detection surface coils: (A) two planar loops and (B) butterfly coil and single loop coil. The image grayscale represents the computed  $B_1$  amplitude in the  $x$ - $y$  plane, while the arrows show the direction of the  $B_1$  fields produced by the two coils. Good quadrature detection occurs in the central region where the fields from the two coils are perpendicular and of similar magnitude. (Reproduced from Haase A, Odoj F, Von Kienlin M, *et al.* (2000) NMR probeheads for *in vivo* applications. *Concepts in Magnetic Resonance* 12: 361–388, with permission of John Wiley & Sons, Inc. Copyright © 2000 Wiley Periodicals, Inc. A Wiley Company.)

complicated designs, the coil may be ‘double-tuned’ to two frequencies simultaneously. It is a challenge to design double-resonant circuits that operate optimally at both frequencies.

### Techniques

Despite a very inhomogeneous spatial distribution of flip angles, many *in vitro* NMR spectroscopy methods can be used with surface coils. For instance, the large  $^1\text{H}$  signal from tissue water may be reduced using the Hore binomial water-suppression sequences (e.g., the  $1\bar{3}3\bar{1}$  or  $1\bar{3}3\bar{1} - 2\bar{6}6\bar{2}$  pulse sequences). Each  $+\theta$  and  $+3\theta$  flip angle in the sequence (denoted by 1 and 3, respectively) has a corresponding  $-\theta$  and  $-3\theta$  flip angle (denoted by  $\bar{1}$  and  $\bar{3}$ ) so that the water magnetization (on resonance) is returned to its initial

orientation parallel to  $B_0$  but the metabolite magnetizations (off resonance) finally have components in the transverse plane and are detected. Other frequency-selective saturation techniques (e.g., DANTE sequences) can be used to suppress unwanted resonances partially (see **Figure 1B**).

Spin-echo techniques ideally require exact  $90^\circ$  or  $180^\circ$  flip angles throughout the sample but may still be used with a nonuniform flip angle, despite some difficulties. Phase-cycling sequences such as EXOR-CYCLE can eliminate disadvantages such as phase and amplitude distortions. Spin-echoes allow  $^1\text{H}$  spectra to be edited and simplified, thereby facilitating measurements of resonances that would otherwise be unresolved owing to peak overlap. Using a double-resonant coil (see above) in  $^{13}\text{C}$  or  $^{31}\text{P}$  studies, applications such as  $^1\text{H}$  decoupling, nuclear Overhauser enhancement, and polarization transfer can all help increase the SNR for  $^1\text{H}$ -coupled nuclei.

Although a surface coil alone can provide sufficient localization for many studies, a second level of localization may be useful for others. Magnetic field gradient coils, commonly used for imaging the subject, also allow collection of spectra from much more specifically defined volumes (voxels). ‘Nonecho localization’ methods such as image-selected *in vivo* spectroscopy (ISIS) and outer-volume suppression (OVS; such as single-shot inversion-recovery based nonecho) are especially useful with surface coils, but the echo techniques point-resolved spectroscopy (PRESS) and stimulated echo acquisition mode (STEAM) may also be used. Selecting a voxel with a smaller volume reduces the SNR of the spectrum, but this is compensated partially by narrower linewidths due to the superior  $B_0$  field homogeneity obtainable with additional localization. With additional localization, the spectroscopic information acquired is much more specific to the target tissue; therefore contaminating signals, e.g., from superficial lipids, are greatly reduced. These gradient-localized methods are especially useful for  $^1\text{H}$  spectroscopy, which has a high intrinsic sensitivity and reveals many overlapping resonances within a relatively small chemical shift range. By adding ‘phase-encoding’ gradients to any of these methods, surface coils may also be used for chemical shift imaging experiments.

PRESS, based on a double spin-echo, requires exact  $90^\circ$  and  $180^\circ$  pulses ideally. However PRESS too can be applied in the inhomogeneous surface coil  $B_1$  field, provided the out-of-voxel signal from non-ideal pulses is removed using phase-cycling schemes and/or large spoiler gradient pulses. The same applies to the stimulated echo sequence STEAM. More complicated versions of PRESS may be implemented

using pairs of adiabatic pulses, such as the hyperbolic secant or frequency offset corrected inversion pulses (FOC1), to obtain a uniform flip angle throughout the voxel. For ISIS, such adiabatic pulses can give good inversions almost independent of  $B_1$ . For OVS methods,  $B_1$ -independent saturation outside the voxel of interest may be achieved using either inversion recovery methods or 'noise' pulses. For  $^1\text{H}$  spectroscopy, these techniques may be combined with water suppression using chemical shift selective (CHESS) pulses. Multiple CHESS pulse schemes have been optimized to give excellent suppression even in inhomogeneous  $B_1$  fields, for a wide range of  $T_1$  relaxation times.

Another consequence of the nonuniform sensitivity of the coil is that quantification of absolute metabolite concentrations is only possible if it is assumed that the underlying metabolite distribution is uniform. Nevertheless, with appropriate handling of relaxation effects, acceptably accurate absolute quantification has been demonstrated. With a coil tuned for a single nucleus, a homonuclear external concentration reference can be employed. Using a double-tuned coil, the signal from the nucleus of interest (e.g.,  $^{31}\text{P}$ ) can be referenced to the  $^1\text{H}$  signal from water, either in the subject or in an external standard. It is also possible to calculate the absolute sensitivity of the coil at a given point in space by using the principle of reciprocity combined with a knowledge of the transmitter pulse amplitude required to produce a  $90^\circ$  flip angle.

## Spectral Data Analysis

The poor  $B_0$  homogeneity encountered *in vivo* may lead to substantial overlap of neighboring peaks, especially at the lower field strengths used commonly for clinical investigations. Rigorous data analysis methods are needed for getting accurate measurements of both peak area and chemical shift despite such overlaps. Ideally, the analysis should be automated and user-independent. Computers have allowed the use of very sophisticated analysis techniques, covering both analysis of spectra and interpretation of the results through pattern recognition approaches like principal component analysis, linear discriminant analysis, or neural network approaches.

A spectrum may be analyzed either in the frequency domain (i.e., the Fourier transform spectrum) or in the time domain (i.e., the raw signal). The simplest methods in both approaches attempt to fit model functions to the different resonances in the spectrum. Typically, the models might be Lorentzian or Gaussian lineshapes in the frequency domain or exponentially decaying sinusoids in the time domain.

The chemical shift, amplitude, phase, and width (or damping factor) are estimated for each peak. In the frequency domain, it is common to 'phase' the spectrum by applying constant and linear phase corrections, determined either automatically or manually.

There have been many improvements on these basic principles, reflected in many sophisticated software packages. Lineshape distortions may be compensated by correcting either the spectrum or the model functions. Broad background features may be fitted using suitable slowly varying functions in the frequency domain or suppressed in the time domain by excluding or damping the first few raw data points. For compounds that produce several resonances or have multiplet resonances, the fits may be constrained using prior knowledge about the relative amplitudes, frequencies, widths, J-couplings (multiplet splittings), and phases of the peaks. Extending this idea, the chosen model functions may be the entire spectrum for each metabolite (either measured from sample solutions or simulated) instead of the individual resonances – this is the basis of the linear combination model (LC model), which analyzes NMR data in the frequency domain. A similar approach may also be applied to time domain data, for example within the readily available magnetic resonance user interface (MRUI) package. Such approaches can however be problematic when the resonance frequencies shift due to changes in  $\text{pH}_i$  or metal ion concentrations.

## Applications

Surface coils have been applied to studies of many tissues in a wide variety of situations, using several different nuclei including  $^{31}\text{P}$ ,  $^1\text{H}$ ,  $^{13}\text{C}$ , and fluorine ( $^{19}\text{F}$ ). Two example applications discussed here are studies of the brain of the newborn infant and cancer.

For clinical applications there are safety guidelines from official national organizations limiting the exposure of staff and patients to static and varying magnetic fields, RF fields, and acoustic noise (from gradient coils). In nonclinical applications these guidelines may often be relaxed unless human volunteers are involved.

### Neonatal Brain, Birth Asphyxia, and Energy Metabolism

In the newborn, the cranial musculature is poorly developed, allowing  $^{31}\text{P}$  surface coil spectroscopy of neonatal brain without additional localization. An extremely broad peak underlies the spectrum, from relatively immobile  $^{31}\text{P}$  nuclei in cranial bone, but this can be removed in postacquisition processing. As

shown in **Figure 1A**, in neonatal brain, strong signals are detected from PME (mainly phosphoethanolamine (PEt)), PDEs (a fairly broad peak originating mainly from cross-linked PDEs in cellular membrane bilayers), and nucleotide triphosphates (NTPs) – mainly ATP. Smaller, clearly resolved peaks due to Pi and PCr are seen also. Several studies of the brains of human infants have demonstrated significant developmental changes in the relative levels of the phosphorylated metabolites detectable in  $^{31}\text{P}$  spectra. As infants develop, the cerebral PCr/Pi and PDE/ $P_{\text{tot}}$  ratios increase, whereas PME/ $P_{\text{tot}}$  decreases ( $P_{\text{tot}}$  is the total mobile phosphate:  $\text{PME} + \text{Pi} + \text{PDE} + \text{PCr} + 3 \times \beta\text{-NTP}$ ). The PME/PDE ratio has been used as an index of brain development.

In infants who have suffered perinatal hypoxic–ischaemic brain injury (birth asphyxia),  $^{31}\text{P}$  spectra obtained within a few hours of birth show no abnormalities. However, in many cases a delayed ‘secondary energy failure’ (SEF) develops within  $\sim 24$  h. The Pi signal increases, accompanied by reduced PCr and, in severe cases, low NTP. Furthermore, in contrast to the profound acidosis seen during acute hypoxia–ischemia, an intracellular alkalosis may be detected. Additionally, localized  $^1\text{H}$  spectroscopy shows elevated lactate levels for several weeks following SEF. Both PCr/Pi and lactate/N-acetylaspartate (Lac/NAA) ratios have proved to be extremely useful indices of the severity of hypoxic–ischaemic injury, with strong prognostic capabilities.

### Cancer

NMR spectroscopy of tumors has become an area of great interest, with  $^{31}\text{P}$  studies in particular showing potential as a noninvasive means of understanding tumor metabolism, to grade tumor malignancy or stage disease progression and to predict the efficacy of particular forms of therapy. Many different types of tumor have been studied, with *ex vivo* and *in vitro* NMR as well as *in vivo*. Most tumor spectra contain strong PME signals, consisting of both PEt and phosphocholine (PCh), with some indications that high levels of PCh may correlate with higher-grade tumors. Pi, PDE, and NTP are also seen, but the levels of PCr are usually much smaller than in many other tissues. Usually, PME increases as the disease progresses, whereas a decrease in PME often gives a clearer and earlier indication of a positive treatment response than reduced tumor volume and could help determine clinical management. The levels of PDE, NTP, and total phosphates can also change significantly. In some sarcomas, the pretreatment pH<sub>i</sub>, measured from the Pi chemical shift, correlates with posttreatment tumor necrosis.

Other nuclei may also be useful for improving our understanding of cancer. Gradient-localized  $^1\text{H}$  spectra have been used in tumor classification, sometimes in conjunction with computer-based ‘pattern recognition’ methods such as principal component analysis. Also,  $^{19}\text{F}$  NMR has been used to assess the uptake of particular cytotoxics such as 5-fluorouracil. Patients who show tumor uptake of  $^{19}\text{F}$ -labeled 5-fluorouracil are more likely to respond to chemotherapy with this agent.

### Other Applications

Skeletal muscle is a classic early example of the use of  $^{31}\text{P}$  surface coil spectroscopy for studying energy metabolism. With a surface coil, muscle metabolism can be monitored easily, not only in unfatigued, resting muscle but also during contraction or ischemia. During exercise, the normally strong PCr signal falls, with a concomitant increase in Pi. If the exercise is severe, ATP may decline. Lactic acidosis is revealed by a reduced Pi chemical shift. In contrast, an alkaline pH change is observed in McArdle’s syndrome, in which glycolysis is inhibited, thereby stopping lactate production.

Despite the difficulties of obtaining an adequate signal from  $^{13}\text{C}$ , which has a natural abundance of only  $\sim 1.1\%$ , it is still possible to use this nucleus for investigating energy storage compounds such as fatty acids and glycogen, e.g., in liver, muscle, or adipose tissue. This can distinguish patients with glycogen storage diseases from normal subjects. Many more compounds can be detected after infusion with  $^{13}\text{C}$ -labeled compounds such as  $^{13}\text{C}$ -glucose, which has been used to investigate glucose storage and metabolism in some detail, especially in patients such as diabetics.

Gradient-localized  $^1\text{H}$  spectroscopy is applied widely in the brain since spectra with good line-widths may be obtained from a specific region. Many pathologies have been investigated, including epilepsy, dementia, multiple sclerosis, stroke, Canavan’s disease, and Huntington’s disease. A common feature of many brain pathologies is a reduced level of NAA (primarily a neuronal marker). Changes in the levels of glutamate, glutamine, myo-inositol, and gamma-aminobutyric acid (GABA) can also be seen in certain pathologies. Spectroscopy has even discovered new syndromes, in particular a deficiency of creatine.

### Trends

Surface coils continue to be used for specific applications in studies of living tissue. In particular, they are proving of great utility for experimental studies in high-field, small-bore spectrometers. Recent and

ongoing developments of spectral editing, data analysis, localization, and RF pulse design enhance the utility of these NMR probes, provided by their high SNR.

## Introduction

*In vivo* nuclear magnetic resonance (NMR) spectroscopy (abbreviated to magnetic resonance spectroscopy (MRS) for clinical purposes) allows the noninvasive assay of metabolite concentrations and provides information about their biophysical/biochemical environment (mainly intracellular). For many applications it is desirable that spectra should be obtained from a well-defined volume of tissue, with minimum contamination from signal originating elsewhere. There are a number of established localization techniques that are used clinically for *in vivo* MRS. Spectroscopic imaging, where spectra are obtained from a matrix of voxels (voxel is an element within a matrix containing spectroscopic information in MRSI), has also become increasingly common. Mainly proton ( $^1\text{H}$ ) and phosphorus ( $^{31}\text{P}$ ) studies are used in the clinical environment. This article describes the localization techniques that are commonly used, the factors affecting spectral quality, and gives some example of their use in *in vivo* MRS.

## Localization Techniques

### Image-Selected *In vivo* Spectroscopy

Image-selected *in vivo* spectroscopy (ISIS) is a multi-shot technique for localization; that is, localization is achieved by the application of several successive pulse sequences. Selective radiofrequency (RF) pulses are used to invert the magnetization in up to three mutually orthogonal slices. Following each inversion sequence a nonselective excitation pulse is applied followed by acquisition of the free induction decay (FID) (Figure 1). Individual FIDs are not localized to the volume of interest (VOI). Instead, the initial inversions modify the eventual phase of the magnetization in the transverse plane. Localization is achieved by acquiring data from eight separate experiments using different combinations of selective inversions. These data are then added or subtracted to each other in accordance with the protocol outlined in Table 1. This protocol ensures that signal from within the VOI adds constructively whereas signal from outside the VOI cancels; thus, localization is achieved. The FID is collected directly following the excitation pulse and so spin-spin relaxation and phase modulation effects are negligible. As a result, this technique has found particular application in  $^{31}\text{P}$  spectroscopy where phase modulation complicates observation of adenosine

ongoing developments of spectral editing, data analysis, localization, and RF pulse design enhance the utility of these NMR probes, provided by their high SNR.

## Introduction

*In vivo* nuclear magnetic resonance (NMR) spectroscopy (abbreviated to magnetic resonance spectroscopy (MRS) for clinical purposes) allows the noninvasive assay of metabolite concentrations and provides information about their biophysical/biochemical environment (mainly intracellular). For many applications it is desirable that spectra should be obtained from a well-defined volume of tissue, with minimum contamination from signal originating elsewhere. There are a number of established localization techniques that are used clinically for *in vivo* MRS. Spectroscopic imaging, where spectra are obtained from a matrix of voxels (voxel is an element within a matrix containing spectroscopic information in MRSI), has also become increasingly common. Mainly proton ( $^1\text{H}$ ) and phosphorus ( $^{31}\text{P}$ ) studies are used in the clinical environment. This article describes the localization techniques that are commonly used, the factors affecting spectral quality, and gives some example of their use in *in vivo* MRS.

## Localization Techniques

### Image-Selected *In vivo* Spectroscopy

Image-selected *in vivo* spectroscopy (ISIS) is a multi-shot technique for localization; that is, localization is achieved by the application of several successive pulse sequences. Selective radiofrequency (RF) pulses are used to invert the magnetization in up to three mutually orthogonal slices. Following each inversion sequence a nonselective excitation pulse is applied followed by acquisition of the free induction decay (FID) (Figure 1). Individual FIDs are not localized to the volume of interest (VOI). Instead, the initial inversions modify the eventual phase of the magnetization in the transverse plane. Localization is achieved by acquiring data from eight separate experiments using different combinations of selective inversions. These data are then added or subtracted to each other in accordance with the protocol outlined in Table 1. This protocol ensures that signal from within the VOI adds constructively whereas signal from outside the VOI cancels; thus, localization is achieved. The FID is collected directly following the excitation pulse and so spin-spin relaxation and phase modulation effects are negligible. As a result, this technique has found particular application in  $^{31}\text{P}$  spectroscopy where phase modulation complicates observation of adenosine

**Figure 1** ISIS. In eight separate acquisitions combinations of up to three frequency-selective RF pulses invert the longitudinal magnetization in three orthogonal slices prior to a nonselective excitation pulse and collection of the free induction decay. The inversion pulses modify the resultant phase of the transverse magnetization existing after excitation. For three-dimensional localization, the inversion pulses are applied and the data added or subtracted according to the protocol in **Table 1**.

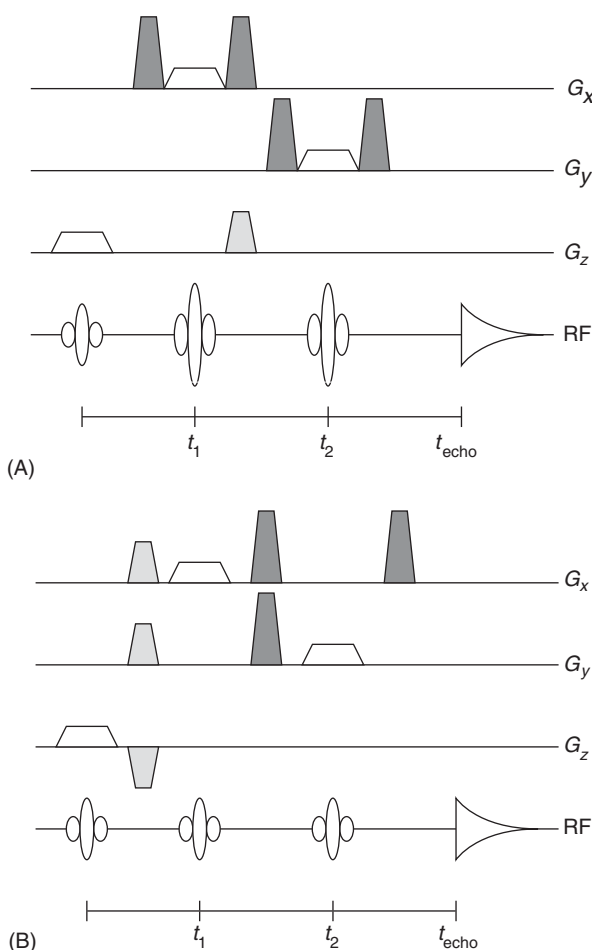

**Table 1** Details of the slice inversion scheme and combination of data for a three-dimensional ISIS localization

Experiment	X-slice inversion	Y-slice inversion	Z-slice inversion	Add/subtract data
1	Yes	No	Yes	Add
2	No	Yes	No	Subtract
3	No	Yes	Yes	Add
4	Yes	No	No	Subtract
5	No	No	Yes	Subtract
6	Yes	Yes	No	Add
7	Yes	Yes	Yes	Subtract
8	No	No	No	Add

triphosphate (ATP). However, because ISIS is a multishot technique, subject motion or receiver instability can degrade localization efficiency resulting in contamination from signal originating outside the VOI.

### Point Resolved Spectroscopy and Stimulated-Echo Acquisition Mode

Point resolved spectroscopy (PRESS) and stimulated-echo acquisition mode (STEAM) use three selective RF pulses in combination with linear field gradients to yield localization of the VOI in a single shot. Thus, the localization provided by these techniques is not degraded by subject motion or system instability. Generally, the use of three RF pulses leads to the formation of five coherent pathways for echo formation. Both PRESS and STEAM are designed to yield a particular echo that is localized to the VOI; the other echoes are suppressed by the use of spoiler gradients and phase cycling of the RF pulses. The

**Figure 2** PRESS (A) and STEAM (B). Both methods use a combination of three frequency-selective RF pulses with linear field gradients in three orthogonal directions to yield VOI localization. Slice selection gradients are unshaded; trim gradients, which ensure zero net de-phasing of transverse magnetization due to the selection gradients, are lightly shaded. A VOI echo is collected during data acquisition (Acq); other echoes are suppressed by phase cycling the RF pulses and spoiler gradients (heavy shading). (A) PRESS uses selective  $180^\circ$  refocusing pulses at times  $t_1$  and  $t_2$ , following an initial excitation, to yield a spin-echo at time  $2t_2 - t_1$ . (B) STEAM uses selective excitation pulses at times  $t_1$  and  $t_2$ , following an initial excitation, to yield a stimulated echo at time  $t_1 + t_2$ . No spin-spin relaxation occurs during the mixing time (TM) – hence  $TE = 2t_1$ .

PRESS sequence consists of an initial excitation pulse (optimally  $90^\circ$  if the magnetization is allowed to fully relax between acquisitions), two refocusing ( $180^\circ$ ) pulses at times  $t_1$  and  $t_2$  after the excitation pulse, and the acquisition of a spin echo at echo time  $(TE) = 2t_2 - t_1$  (**Figure 2A**). The STEAM sequence consists of an initial excitation pulse, two  $90^\circ$  pulses at times  $t_1$  and  $t_2$  after the excitation pulse and the acquisition of a stimulated echo at  $t_1 + t_2$  (**Figure 2B**). In STEAM, the period between the second and third pulses is often termed TM – the ‘mixing’ time

(see Figure 2B); spin-spin relaxation does not occur during TM and hence,  $TE = 2t_1$ . Both PRESS and STEAM are subject to spin-spin relaxation of signal and phase modulation effects. Typically, these sequences are used for  $^1\text{H}$  MRS because the  $^1\text{H}$  resonances of mobile metabolites have relatively long  $T_2$ s. However, short  $TE$ s of  $\sim 10$  ms are easily achievable with PRESS and with STEAM even shorter effective  $TE$ s are achievable. Because phase modulation effects are different for PRESS and STEAM the metabolites of interest are leading determinants of which sequence and  $TE$  to use. Short  $TE$   $^1\text{H}$  spectra have a better signal-to-noise ratio (SNR) and less phase modulation effects than long  $TE$  spectra; the former are most useful for studies where absolute quantification of metabolite concentrations is required. However, signals from macromolecules and lipids, which have short  $T_2$ s, produce an undulating baseline in short  $TE$  *in vivo* spectra, which can greatly complicate the spectral analysis. For this reason, it is often desirable to use longer  $TE$ s in order to simplify spectra. PRESS has an intrinsic two-to-one advantage in SNR over STEAM because of the collection of a spin echo. However, at a given  $TE$  and for a particular multiplet resonance of interest, phase modulation effects may reduce the SNR advantage of PRESS.

### Outer-Volume Suppression

Instead of exciting only the spins in the target VOI, a signal can be localized by selective suppression of the signal from the rest of the sample. Selective RF pulses are used to flip longitudinal magnetization in the regions outside the VOI into the transverse plane. This transverse magnetization is then de-phased by the application of spoiler gradients so that no net magnetization remains outside the VOI. After the application of six appropriately positioned and orientated suppression slices longitudinal magnetization remains unaffected within the VOI and localized spectroscopic information can be acquired by using a simple nonselective excitation followed by collection of the FID. Like PRESS and STEAM, outer-volume suppression (OVS) is a single-shot technique and is, therefore, resilient to subject movement and system instability. However, because data are acquired with a single nonselective excitation pulse, OVS, like ISIS, has advantages for the collection of data from short  $T_2$  metabolites. Suppression of longitudinal magnetization outside the VOI must be extremely efficient to avoid significant contamination of the resulting spectrum. OVS can also be used in combination with most other localization methods (e.g., OSIRIS combines ISIS with OVS) thereby greatly improving localization efficiency.

### Magnetic Resonance Spectroscopic Imaging

The techniques described above are generally used to obtain data from a single VOI. Magnetic resonance spectroscopic imaging (MRSI) has the advantage of generating a matrix of voxels, each containing spectroscopic information. Thus, the spatial distribution of any metabolic abnormalities can be assessed from a single MRSI data acquisition. Furthermore, post-processing of the spectra can yield maps of the concentration of individual metabolites, metabolite ratios, or any other measurable (e.g., intracellular pH ( $\text{pH}_i$ )) and so morphological magnetic resonance imaging (MRI) can be correlated to maps of tissue metabolism. MRSI data are acquired by using a single-shot pulse sequence with the addition of spatial phase-encoding gradients. A simple pulse-acquire acquisition scheme is easily modified with the addition of phase-encoding gradients in three orthogonal directions – three-dimensional MRSI (Figure 3). Fourier transforming, the  $k$ -space data along the phase-encoding dimensions, leaves a three-dimensional matrix of FIDs; a further Fourier transform yields the final matrix of spectra. The data acquisition can be restricted to a VOI defined by using slice selection or a voxel localization technique, such as PRESS or STEAM, in place of the nonselective excitation pulse in the above example. The matrix of voxels can then be restricted to one or two dimensions by phase encoding in only one or two directions if required and thus be tailored to suit the morphology of the tissue being studied. Reducing the

**Figure 3** MRSI. Phase-encoding gradients localize spectra to a matrix of voxels within a volume of tissue. A nonselective hard pulse may be used to excite the entire sample prior to phase encoding or a localization technique, such as PRESS, can restrict data acquisition to a VOI to reduce lipid contamination. Phase encoding may be restricted to one or two dimensions if required.

number of phase-encoding steps also reduces the total acquisition time.

The acquisition details of an MRSI experiment are predominantly governed by the sensitivity of the imaging apparatus to the nucleus of interest and the practical limitations of time imposed on the experiment due to the tolerance of the subject or the time-scale of the dynamic metabolic processes that are being monitored. The low intrinsic sensitivity of the  $^{31}\text{P}$  nucleus and the fact that only single nuclei contribute to most resonances means that  $^{31}\text{P}$  voxels must be substantially larger than can be used for  $^1\text{H}$ . A typical  $^{31}\text{P}$  matrix would consist of  $16 \times 16 \times 1$  voxels each with a volume of  $\sim 8\text{--}27\text{ cm}^3$ . The greater sensitivity of  $^1\text{H}$  allows better spatial resolution; typically  $32 \times 32 \times 1$  voxels each with a volume  $\sim 1\text{--}8\text{ cm}^3$ . However,  $^1\text{H}$  matrix sizes are still small, and the spatial resolution consequently worse, compared to standard MRI techniques. As a result of the small number of phase-encoding steps the size of the point spread function (PSF) is increased; the PSF is a sinc function and widened side-bands can result in serious voxel contamination. In order to minimize this effect, a filter (e.g., Hanning) is usually applied to the data, although at the cost of decreasing the effective spatial resolution.  $^1\text{H}$  MRSI presents further challenges: water suppression and the avoidance of contributions from subcutaneous fat. Good water suppression depends upon good shimming (i.e., homogenization of the static magnetic field) throughout the matrix; this consideration is dealt with in the next section. Lipid signal can be avoided by restricting the data acquisition to regions within the organ of interest – for example, by phase encoding within a PRESS VOI.

## Factors Affecting Localization and Spectral Quality

### Sensitivity – Field Strength and Coil Performance

One of the most significant factors affecting spectral quality is the sensitivity to the nucleus of interest. The maximum available signal is proportional to almost the square of the main magnetic field strength and it is this factor that principally governs the sensitivity of the experiment. Increasing the field strength from 1.5 to 3 T allows for the same level of signal to be obtained either from about a quarter the volume of tissue or in substantially less scanning time. Increasing field strength generally requires a new magnet and, of course, this is an expensive option. Contributions to the RF noise component of the detected signal are important. These come from various sources, but the dominant contributor is the inductive coupling between the coil and the sample.

The whole of the sample within the sensitive volume of the coil contributes to the noise in the spectrum whereas localized signal originates only from the VOI. An appropriate RF coil design is important to the success of the investigation. Among the factors that influence the optimal coil design are the location and size of the VOI within the sample and the choice of localization methodology. Volume coils that can accommodate large parts of the human body have the advantage of a relatively homogeneous  $B_1$  field over their sensitive volume. Surface coils, in comparison, have a limited sensitive volume, significant  $B_1$  gradients, and are most useful for peripheral applications. However, in certain appropriate applications, surface coils typically yield localized spectra with a greater SNR than that obtained using volume coils – but to achieve this the target VOI must be close to the surface. The main disadvantage of a surface coil is the highly inhomogeneous  $B_1$  field. Unless a VOI is small compared to the dimensions of the coil, there will be a large variation in both flip angle and sensitivity over the VOI. As a consequence, phase modulation effects and signal strength will vary leading to difficulties in absolute quantitation. Furthermore, surface-coil  $B_1$  inhomogeneity may contraindicate the use of larger VOIs because a particular localization technique may require exact inversion pulses. Water suppression is essential for  $^1\text{H}$  MRS in order to digitize the low molarity metabolite signals –  $B_1$  inhomogeneity can drastically reduce the efficiency of water suppression schemes. However, these problems can be addressed by the use of adiabatic RF pulses, which are discussed in a later section.

### Chemical Shift Displacement Artifact

Localization of the NMR signal is achieved through the use of magnetic field gradients to encode spatial information in the frequency of the RF signal. Signals from nuclei in various metabolites resonate at different RFs: these are termed ‘chemical shifts’ and for simplicity are expressed as parts per million of the static magnetic field strength (ppm). A consequence of metabolite signals occurring at discrete chemical shifts is that each resonance will originate from its own discrete VOI, which will be displaced spatially with respect to VOI for resonances at other chemical shifts (Figure 4). This is called the ‘chemical shift displacement artifact’ (CSDA) and this effect has important repercussions for most localized spectroscopy methods. Spectrum analysis often involves calculating the ratio of two particular metabolites (e.g., lactate (Lac)/N-acetylaspartate (Naa)). Information is acquired from two VOIs, one for each

**Figure 4** The chemical shift displacement artifact. (A) An applied linear magnetic gradient encodes spatial position in the resonant frequencies of two particular spectrum peaks (represented by the sloping lines). Peak 1 has a different chemical shift to peak 2. A selective RF pulse, centered on frequency  $f_0$  and with bandwidth  $\Delta f$ , will excite a slice at a different position for each peak as shown. (B) Increasing the strength of the linear magnetic gradient reduces the difference in slice position – however, to achieve slices with the same spatial width as in (A), a larger bandwidth RF pulse must be used.

metabolite, which occupy different spatial positions and the measured ratio may be unrepresentative of the true value in the nominal VOI. This problem is accentuated for  $^{31}\text{P}$  spectra where the chemical shift range across the spectrum is  $\sim 25$  ppm resulting in much greater spatial displacements of the VOI. CSDA is not a problem in three-dimensional MRSI unless spatially selective pulses are used. However, whenever slice or volume selection is employed for MRSI, the position of the slice or volume is chemical-shift dependent. CSDA can inhibit the effects of phase modulation that will only occur where the discrete VOIs for the two coupled resonances intersect. A further consequence of CSDA when used with a surface coil is that, due to inhomogeneous  $B_1$ , signal amplitude will change with chemical shift because of the variable VOI location.

### Design of RF Pulses

Some of the problems of  $B_1$  inhomogeneity and CSDA can be addressed with the use of specially designed RF pulses. Adiabatic pulses, and in particular a subset known as hyperbolic-secant (SECH) pulses, have desirable properties for many spectroscopic applications. A ‘full-passage’ SECH pulse modulates the frequency as well as the amplitude of the RF such that longitudinal magnetization is fully inverted at the end of the pulse, regardless of  $B_1$  inhomogeneity within certain thresholds. In order for these pulses to work, an adiabatic condition must be met, which places a lower limit on the RF power required. However, with careful design SECH pulses can be used *in vivo* without exceeding RF power

**Figure 5** Examples of the frequency profiles of a SECH pulse and a three-lobe sinc pulse. The SECH pulse has far less prominent side-bands than the sinc. The profiles were generated on a 2.4 T Bruker Avance Scanner at University College London.

deposition limits. The ability to perform an adiabatic inversion with an inhomogeneous  $B_1$  field is beneficial when using ISIS with a surface coil; good inversion across the whole VOI greatly improves the SNR. The frequency bandwidth of an SECH pulse is modulated by the frequency sweep within the pulse and has a sharply defined profile with minimal side-bands compared to conventional sinc or Gaussian shaped pulses (Figure 5). Pulses that have very large bandwidths can be designed (10 kHz or more). The larger the bandwidth of the pulse, the larger the magnetic field gradient required to localize a VOI of a given size. Large bandwidth RF pulses require large magnetic field gradients and the latter are advantageous

in reducing CSDA. The main limitation in using adiabatic pulses is not generally the maximum available magnetic gradient strength but rather the maximum RF power that can be safely applied to the subject; pulses designed with larger frequency sweeps and consequently broader bandwidths require higher RF powers to achieve the adiabatic condition. A solution is to use frequency offset corrected inversion (FOCI) pulses. FOCI pulses utilize time-dependent shaped magnetic gradient waveforms during application of an SECH pulse. Spin inversion occurs at different times for different frequencies. The gradient waveform is shaped so that it is maximum when slice edges are being inverted. Thus, pulses require smaller bandwidths and hence lower powers. As a result of the use of adiabatic pulses with surface coils the effects of many pulse sequences are largely CSDA-independent and leading to less chemical shift dependence of signal strength.

### Localized Shimming and Water Suppression

*In vivo* spectrum quality is strongly influenced by the homogeneity of the static magnetic field within the VOI. Shim coils are used to produce shaped magnetic fields that cancel inhomogeneities in the main field. This process of shimming can greatly improve the chemical-shift resolution of *in vivo* spectra. Spectral resolution is optimized if the actual VOI is shimmed. For single-shot techniques such as PRESS and STEAM, it is only necessary to monitor the  $^1\text{H}$  water signal whilst adjusting the shim-coil currents. For shimming ISIS VOIs, it is necessary to use either OVS, to restrict the signal to the VOI, or to use a single-shot technique. Shimming can be performed manually, where the operator adjusts the currents in the shim coils whilst monitoring the  $^1\text{H}$  water signal; the aim is to minimize the rate of exponential decay of the FID and, hence, reduce static magnetic field inhomogeneities. An alternative is to use an automated technique. A commonly used technique is FASTMAP, which maps the magnetic field along six projections within the defined VOI. Using these data, the required current amplitudes in the shim coils are calculated analytically.

A good VOI shim is a prerequisite to addressing a further problem in  $^1\text{H}$  spectroscopy: the strong signal from tissue water: it is difficult to adequately digitize the signals from low molarity ( $\sim 10 \text{ mmol l}^{-1}$ ) metabolites in the presence of a large signal from tissue water ( $\sim 45 \text{ mol l}^{-1}$ ). Localization sequences are often preceded by chemical-shift-selective (CHESS) pulses, which are used in conjunction with spoiling gradients to selectively saturate the water signal.  $B_1$ -insensitive techniques for water suppression such as

BISTRO, which uses specially designed adiabatic pulses, are also available and are of particular use in surface coil studies.

### Line-Shape Corrections

Gradient-pulse-induced eddy currents can distort the line shapes of spectral peaks, particularly in short TE spectra. This problem can make spectra difficult to analyze because analytical fitting functions may not be appropriate. The use of high-performance gradient coils with very short rise and fall times can minimize eddy currents. However, postprocessing of spectra, using a phase-correction derived from an unsuppressed water peak, can improve the quality of spectra where eddy-current-induced distortion is apparent.

### Absolute Quantification of Metabolite Concentrations

*In vivo* spectra are often analyzed to give metabolite peak-area ratios: these can be simply and even automatically obtained from available analysis packages. However, rigorous interpretation of an abnormal peak-area ratio is difficult if the observer is unaware which metabolite concentration has changed – or maybe both have changed but by differing amounts. Furthermore, unless data are acquired fully relaxed (repetition time  $> 5T_1$ ) with very short TE (or by ISIS or OVS) peak-area ratios can be modulated by changes in  $T_1$  or  $T_2$  relaxation ( $T_1$ : spin-lattice relaxation time – characteristic time for recovery of longitudinal magnetization and  $T_2$ : spin-spin relaxation time – characteristic time for de-phasing of magnetization in the transverse plane). Absolute quantification of metabolite concentrations has specific requirements in order to be successful: the *in vivo* signal amplitude must be normalized for VOI size and numbers of resonating nuclei per resonance, a stable concentration reference (external or internal) must be available, differences in signal amplitude due to variations in coil loading must be correctable, and, with surface coils, variations in signal amplitude resulting from  $B_1$  inhomogeneity and CSDA must be addressed.

In brain studies a significant part of the VOI may be occupied by cerebrospinal fluid (CSF), which is largely water and contains only small quantities of detectable metabolites. In order to determine the VOI fraction occupied by brain tissue, detailed three-dimensional MR imaging datasets may be used. Alternatively, since CSF  $T_2$  is long compared to that of brain water, measuring the un-suppressed water signal as a function of TE allows separation of the brain-water and CSF components and determination of their individual VOI fractions.

A commonly used internal concentration reference (ICR) is the tissue water itself. Reference spectra (without water suppression) are acquired from the same VOI as the metabolite spectra; factors such as the sensitivity profile across the VOI and the degree of coil loading are thus the same for both spectra – hence, there is mutual cancellation of many factors that would otherwise need to be taken into account. However, the concentration of the ICR must be known *a priori* and pathological variations can lead to inaccuracy. If an external concentration reference (ECR) is used, this can be positioned adjacent to the subject and within the sensitive volume of the RF coil. In this configuration, coil loading for the ECR and subject are identical. However, RF coil sensitivity may be significantly different at the ECR and the VOI. A further approach is to acquire reference data from the ECR in a separate experiment. The coil loading with just the ECR in the RF coil will often be different to the *in vivo* situation and a correction may be necessary. A loading phantom (typically containing a high concentration of sodium chloride) can be introduced in order to match the loading conditions between the two experiments. An alternative is to use the principle of reciprocity, which implies that for a given spin density within a particular VOI the product of the pulse amplitude for a given excitation flip angle and the consequent signal amplitude is a constant. This principle can be used to correct for differences in coil loading between *in vivo* and ECR experiments. The optimum voltage of a water suppression CHESS pulse can be defined much more precisely than, e.g., an optimal excitation pulse and the former is thus a better index of coil loading. When an optimal water-suppression pulse voltage,  $V_1$ , is applied, the water magnetization is rotated through an angle  $\phi_1 = 90^\circ + x$ . A second optimal pulse voltage for suppression,  $V_2$ , exists corresponding to a flip angle of  $\phi_2 = 270^\circ - x$ . Since  $V_1 = k\phi_1$  and  $V_2 = k\phi_2$  where  $k$  is the proportionality constant for the VOI concerned:

$$\phi_1 = \frac{360^\circ}{(1 + (V_2/V_1))}$$

$V_1$  and  $V_2$ , and hence  $\phi_1$ , can be accurately determined during *in vivo* and ECR experiments, thereby enabling precise correction of the effects of coil loading on the signal amplitude. The metabolite concentration,  $n_m$ , can then be calculated by comparing the metabolite peak area,  $A_m$ , to the ECR peak area,  $A_c$  (concentration  $n_c$ ):

$$n_m = n_c \cdot \frac{A_m}{A_c} \cdot \frac{f_c}{f_m} \cdot \frac{T_m}{T_c} \cdot C_{\text{loading}}$$

where  $C_{\text{loading}}$  is the correction for coil loading:

$$C_{\text{loading}} = \frac{V_{1m}}{V_{1c}} \cdot \frac{\phi_{1c}}{\phi_{1m}}$$

The subscripts c and m correspond to the concentration reference and the *in vivo* metabolite respectively,  $f$  is the number of equivalent nuclei contributing to the ECR/metabolite signal, and  $T$  is the *in vivo*/ECR temperature. The *in vivo* and phantom VOI volumes are assumed equal.

## Applications

Because of its noninvasive nature, MRS is especially suited to *in vivo* studies of brain. Numerous cerebral metabolites are detectable, particularly with  $^1\text{H}$  MRS (Figure 6). A few metabolites contribute prominent peaks and these are most easily quantifiable. Naa is predominantly found in the central nervous system, especially in neurons, although its functional role is not fully understood. Dynamic changes in brain Naa concentration have been observed; reduced concentration may indicate neuronal dysfunction as well as loss. A prominent peak due to choline (Cho) has contributions from several metabolites including phosphorylcholine and glycerophosphorylcholine. Phosphatidylcholine is synthesized from choline and is a major constituent of cell membranes; being bound, this component is NMR invisible due to a very short  $T_2$ . Pathologically increased membrane

**Figure 6** A  $^1\text{H}$  MRS spectrum from normal human brain at 7 T. An 8 ml VOI was localized in the parietal white matter using STEAM with effective TE 6 ms, repetition time 5 s, TM 32 ms, and the collection of 160 averaged echoes. Outer volume suppression, employing SECH pulses, was used and FASTMAP was used to shim the VOI. Peaks undefined in the main text are: *myo*-inositol – *myo*-Ins; taurine – Tau; glutathione – GSH; aspartate – ASP; *N*-acetylaspartylglutamate – NAAAG; macromolecule – MM. (Reprinted with permission from Tkáč I, Anderson P, Adriany G, *et al.* (2001) *In vivo*  $^1\text{H}$  NMR spectroscopy of the human brain at 7 Tesla. *Magnetic Resonance in Medicine* 46: 451–456; © Wiley-Liss, a subsidiary of Wiley.)

turnover is thought to result in raised levels of NMR visible Cho. Creatine (Cr) is synthesized in the liver and is phosphorylated to phosphocreatine (PCr) by creatine kinase. In  $^1\text{H}$  MRS a co-resonating Cr and PCr signal is seen and total Cr (i.e.,  $\text{Cr}_{\text{total}} = \text{Cr} + \text{PCr}$ ) has often been used as a reference for the comparison of peak-area ratios such as  $\text{Naa}/\text{Cr}_{\text{total}}$ . However, care must be taken when interpreting such data since neither the  $\text{Cr}_{\text{total}}$  concentration nor the effective  $T_2$  of the co-resonating Cr and PCr components may remain constant with respect to pathology. The Lac concentration is too low to be easily detected in healthy adult brain tissue but Lac is detectable in term and preterm neonates. Lac appears in increased concentrations in pathologies that lead to failed oxidative metabolism or increased glycolysis. Measurements of the concentrations of neurotransmitters such as glutamate, glutamine, and  $\gamma$ -aminobutyric acid (GABA) also have use in studies of various neurological conditions.

$^{31}\text{P}$  *in vivo* spectra are less complex (Figure 7). ATP is the principal donor of free energy in biological systems: the Na/K pump, responsible for maintaining intracellular water content/nerve signal transmission, and muscle contraction are all dependent on ATP. When involved in these vital processes ATP is hydrolyzed to adenosine diphosphate (ADP) and inorganic phosphate (Pi) during which a large

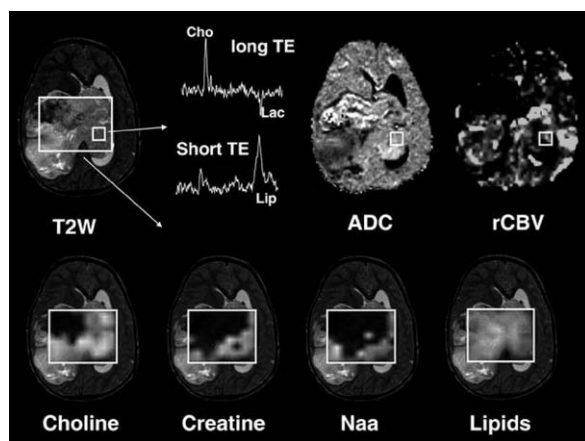

amount of free energy is liberated. In addition to generation by other metabolic pathways, if levels fall ATP can be rapidly regenerated by rephosphorylation of ADP by PCr. Three prominent ATP multiplet resonances are seen:  $\gamma$ -,  $\alpha$ -, and  $\beta$ -ATP (two doublets and a triplet, respectively). PCr and Pi are detected as prominent singlet peak: the Pi chemical shift is pH dependent.  $^{31}\text{P}$  MRS thus provides a window on tissue energy metabolism. Phosphomonoesters (PME) and phosphodiesteres (PDE) are also visible and are related to membrane synthesis.

A good example of the prognostic and diagnostic utility of both  $^1\text{H}$  and  $^{31}\text{P}$  MRS is their use in perinatal asphyxia. A significantly increased Lac/Naa peak-area ratio and/or reduced PCr/Pi in the first few days after birth is associated with impaired neurological development with disability at age 1 year.

Further applications of MRS allow the identification and grading of cancer tissue; brain tumors often display increased Cho, reduced Naa, and the presence of Lac and mobile lipids. The use of MRSI is particularly advantageous; tumors are often heterogeneous in structure and MRSI offers the ability to analyze different parts of a lesion separately (Figure 8). Differentiation between certain brain tumors and between infiltrative and circumscribed lesions can be made based on changes in metabolite ratios across the lesion and in surrounding tissue. Voxels may also be added together to match the anatomical shape of the lesion.

**Figure 7** A  $^{31}\text{P}$  MRS spectrum from neonatal brain at 2.4 T. A 125 ml VOI, localized using PRESS, was centered on the thalami. Acquisition parameters were: TE 10 ms; repetition time 12 s; 160 averaged echoes. The numbered peaks are: 1 PME; 2 extracellular and intracellular Pi; 3 glycerolphosphorylethanolamine and GPC; 4 PCr; 5, 6, and 8  $\gamma$ -,  $\alpha$ -, and  $\beta$ -NTP; 7 nicotinamide dinucleotides and uridine diphosphosugars. **Figure 8**  $^1\text{H}$  MRSI of brain. The T2-weighted image shows a large brain tumor in a 4-year-old boy. The large white rectangle denotes the MRSI VOI preselected using PRESS. Metabolite maps of Cho, Cr, Naa, and lipids are shown. Necrotic regions are characterized by a lack of metabolites; Cho and/or Cr are seen in regions of viable tumor. Also shown are maps of apparent diffusion coefficient (ADC) and cerebral blood flow (rCBF). (Reproduced with permission from Tzika AA, Astrakas LG, Zarifi MK, et al. (2003) Multiparametric MR assessment of pediatric brain tumours. *Neuroradiology* 45: 1–10; © Springer.)

Resonance attributes can be modulated by intracellular biophysical conditions. For example,  $^{31}\text{P}$  MRS can be used to measure  $\text{pH}_i$  by measuring the chemical shifts of Pi and other peaks (e.g., ATP). Alkaline  $\text{pH}_i$  is indicative of a poor prognosis following perinatal asphyxia.  $^1\text{H}$  spectra can be used to measure local brain temperature by comparing the chemical shift of the un-suppressed water peak, which has a relatively strong temperature dependence due to the hydrogen bonding between molecules, with those of Naa, Cho, and Cr. This property may be combined with MRSI to yield temperature maps of the brain.

### Introduction

Techniques for separation of DNA and RNA provide powerful tools for the analysis of genetic material and transcription products. Modern methods of analysis can answer most of the questions about the sequence, nucleotide substitutions (mutations, polymorphisms, or single nucleotide polymorphisms – SNPs), and structure of nucleic acids. Crucial techniques in the analysis of DNA or RNA are the

**Table 1** Chromatographic techniques used in nucleic acid analysis

<i>Chromatographic technique</i>	<i>Mobile phase</i>	<i>Stationary phase</i>	<i>Principle</i>
Size exclusion (SEC)	DNA fragments in a buffer	Silica or polymer particles containing a suitable size distribution of pores	Separation according to DNA fragment effective size
Ion exchange (IEC)	DNA fragments in a buffer	Positively charged groups of the anion-exchange resin	Differences in DNA charge characteristics, which depend on molecular mass
Reversed phase and hydrophobic interaction	Hydrophobic alkyl alkylammonium chain bound to the negative phosphates of DNA	Hydrophobic matrix surface	Hydrophobic interactions
Hydroxyapatite chromatography	Single- and double-stranded DNA	Hydroxyapatite solid surface	Single- and double-stranded DNA have different interaction affinities with hydroxyapatite

traditional separation methods – chromatography and electrophoresis – and, more recently, microfluidics and chip-based DNA arrays and mass spectrometric methods.

Chromatographic methods are commonly used in a variety of single-use kits for the isolation of genomic DNA from debris in a cell lysate. Electrophoresis, on the other hand, plays an essential role in the analysis of the structure, sequence, and function of DNA and RNA because of the high resolution achievable. Recently, however, new protocols were developed for chromatographic DNA separations suitable also for analytical separations, especially for fast and highly efficient analysis of DNA mutations.

## Chromatographic Methods

The chromatographic methods are based on a variety of possible interactions of single- and double-stranded DNA chains with the stationary phase of the chromatographic column. Various forms of chromatographic interactions can be used for the purification of the DNA preparations. A number of single-use cartridges for desalting of the DNA fragments prepared by polymerase chain reaction (PCR) or DNA sequencing reactions are currently available in the market. Measurement of the ultraviolet (UV) absorbance at 260 nm can be employed to determine concentrations of nucleic acids. The ratio of absorbance at 260 and 280 nm is used as an estimate of DNA content relative to the protein concentrations. Usually, at a ratio of >1.9 the DNA preparation is considered to be >99% pure.

The most commonly employed chromatographic methods in nucleic acid analysis are based on size exclusion, ion exchange, reversed phase and

hydrophobic interaction, hydroxyapatite (for the purification and characterization of single- and double-stranded DNA), and liquid-liquid partitioning. The various types of chromatographic separation used for nucleic acids are summarized in **Table 1**.

While some of the separation principles listed in the **Table 1** have only a limited analytical use now and are employed mainly for sample preparation prior to consecutive electrophoretic analysis, the reverse-phase-based separations still represent an important analytical separation tool.

Reversed-phase and hydrophobic-interaction chromatographies are based on very similar types of interaction; in both techniques the nucleic acid is adsorbed to a hydrophobic surface of the chromatographic stationary phase. However, different hydrophobic parts of the nucleic acid are involved in the interaction. Reversed-phase chromatography is an extension of partition chromatography, and in the case of nucleic acids an alkylammonium ion is added to the mobile phase in order to mask the negative phosphates of the nucleic acid, and, thus, obtain retention on the column. Owing to 'ion pair' formation, reversed-phase chromatography of nucleic acids is often called ion pair chromatography. Thus, the nonpolar nucleic acid ion pairs in solution are partitioned on to the bonded hydrophobic matrix phase through the interaction of nonpolar functional groups of both the sample and the sorbent. The solubility of the DNA solute in the mobile phase versus the stationary phase determines the elution order, with the most hydrophobic species eluting last. The adsorbed nucleic acids are generally eluted using an increasing gradient of organic solvents, typically acetonitrile or isopropanol. With the use of nonporous polystyrene-divinylbenzene particles the technique is

capable of analyzing PCR products according to their chain length up to a size of 500 base pairs within a few minutes.

In hydrophobic-interaction chromatography, nucleic acids are adsorbed to the hydrophobic surface by salting out from the aqueous mobile phase. The adsorbed nucleic acids are eluted by a decreasing salt gradient that redissolves the nucleic acids in the aqueous mobile phase. The hydrophobic interaction between a DNA molecule and the matrix is enhanced by high ionic strengths. This makes hydrophobic interactions an ideal tool for purification of DNA molecules that have been prepared in a high salt concentration.

While most of the older chromatographic methods for DNA analysis have been substituted by the more efficient electrophoretic techniques (see later), some newly developed liquid chromatography methods are regaining popularity, especially for rapid analysis of the double-stranded DNA. Thus, denaturing high-performance liquid chromatography (DHPLC) has emerged as one of the most versatile technologies for the analysis of genetic variations. DHPLC has been under development since the mid-1990s and has become a method of choice for the screening of mutations and SNPs. With the development of novel polymer chemistries used for separation, the accuracy, sensitivity, and throughput of DHPLC for DNA and RNA analysis have greatly improved. In addition, the high sensitivity of DHPLC combined with the accuracy of heteroduplex analysis has allowed the development of applications beyond the scope of traditional sequencing or genotyping, e.g., the early detection of cancer. The separation is performed under partial denaturation conditions, which amplifies the differences in the nucleotide hydrogen bonding. This allows separation of long DNA chains differing by only a single nucleotide. Besides requirements on the gradient elution reproducibility, a stringent temperature control is critical for achieving good performance. An example of the DHPLC analysis of 563 base pairs (bp) long PCR products obtained from different ecotypes of *Arabidopsis thaliana* is shown in Figure 1.

An important feature of the DHPLC is the ease of collecting fractions for consecutive DNA sequencing. High-throughput applications (e.g., for screening purposes) are assured not only by the inherent speed of the technique, but also by the recent development of multicolumn automated instrumentation.

## Electrophoretic Methods

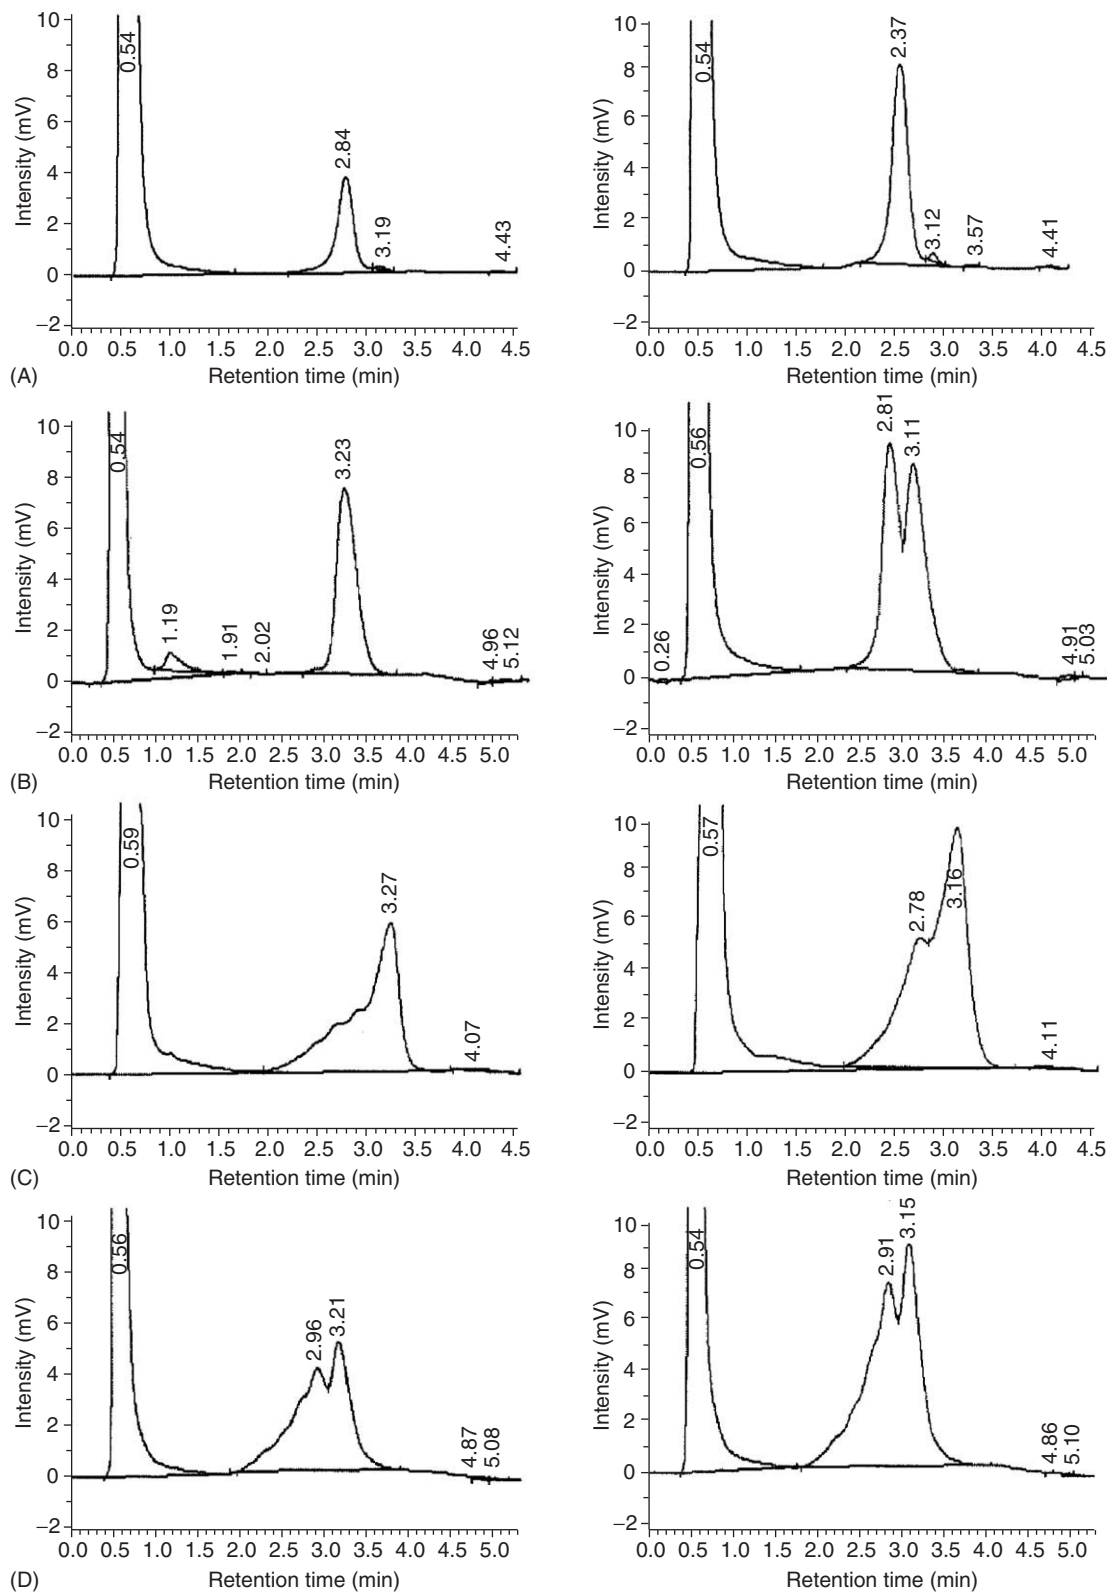

Electrophoresis is a key separation technique for the analysis of nucleic acids. Typically performed

in a bed of hydrophilic gel or in a channel filled with a viscous polymer solution, the separation is based on differential migration of the nucleic acid strands through the pores of the gel. The driving force is the electric field applied across the separation path. Although successfully practiced in the slab gel form for over 50 years, the most successful development of the capillary electrophoresis (CE) mode of the technique was triggered by the sequencing of the human genome. Up to 384 samples can now be analyzed in parallel in an array of the separation columns to achieve the required throughput. Additional improvements of the technique are under way in the form of micromachined microfluidic systems.

The most important feature of CE is the analysis speed and separation efficiency. Electric field strengths as high as  $1 \text{ kV cm}^{-1}$  (as compared to  $\sim 10 \text{ V cm}^{-1}$  typical in the slab gel) can be used in narrow capillaries without overheating. Consequently, analysis time of CE is typically more than an order of magnitude shorter than in the conventional slab gel electrophoresis (SGE). Filling of the separation capillaries with fresh separation matrix prior to each analysis provides defined and reproducible conditions for each run. Fully automated instruments are available. With the help of the capillary sequencers, the goal of the Human Genome Project, to sequence  $\sim 3$  billion base pairs of human DNA was achieved well before the schedule. The combination of the ultrasensitive laser-induced fluorescence detection (LIF) with CE opened enormous possibilities for molecular clinical diagnostics. The total separation volume of a few microliters, sample volumes as low as a few nanoliters together with the high-sensitivity LIF detection enable the analysis of the content of a single cell or even the detection of a single DNA molecule. The substantial improvement in the throughput of analyses in the combination with multiplex PCR or sequencing reactions make the technique suitable for large-scale clinical screening, sequencing, and research applications.

## Gel Electrophoresis

Since the mass-to-charge ratio of DNA molecules is size independent, the electrophoretic velocities of DNA fragments in a free solution are also the same. Therefore, a sieving medium must be used to provide the required separation. The term sieving medium relates not only to physical or chemical gels, but also to a variety of solutions of linear polymers. During the migration the chains of the nucleic acids are selectively retarded by a network of macromolecular obstacles due to the differences in their sizes and

**Figure 1** Characteristic monomorphic (A and D) and polymorphic (B and C) DHPLC profiles obtained upon the analysis of mixtures of denatured and renatured Columbia and Landsberg erecta products (right column). The left column shows profiles of only Columbia fragments that served as monomorphic controls. Parallel analysis of monomorphic controls facilitates the recognition of subtle changes in chromatographic profiles (row C) indicating the presence of mutation(s) and minimizes false positives that are caused mostly by runs of bases or short variable tandem repeats (row D). Analyses were performed at column oven temperatures of 51°C (A), 46°C (B), and 58°C (C and D). (Reproduced with permission from Spiegelman JI, Mindrinos MN, and Oefner PJ (2000) High-accuracy DNA sequence variation screening by DHPLC. *BioTechniques* 29: 1084–1092; © Eaton publishing.)

conformation. To describe the retardation in terms of the dependence of effective mobility on the gel concentration, three migration regimes may be distinguished. If a DNA polymer coil adopts a conformation with the radius of hydrodynamic equivalent sphere,  $R_g$ , smaller than the average mesh size,  $S$ , of the network, the migration is controlled by accidental interactions of the coil with obstacles of a sieving medium. Here, the polymer coil can be considered to be a rigid sphere undergoing biased Brownian movement. The separation under this condition has been explained by a sieving model, where the mobility is regarded as inversely proportional to the probability of the molecule's interaction with the fibers forming the porous network. In this regime, called also Ogston migration, a spherical particle collides with the network at only one place at a time, i.e., the polymer chain is not entangled with the sieving matrix.

Rather different is the migration of a polymer chain of a length comparable with the mesh size. From time to time, the molecule gets hooked and unravels like a rope sliding over a pulley. The velocity of such a migration, which resembles reptile motion, is strongly dependent on the chain size. This mechanism of electromigration is called biased reptation. In this migration regime, the most pronounced drop of the electrophoretic mobility with the molecular mass is observed. In other words, the separation selectivity is the highest here. According to this model, the mobility of a flexible molecule migrating by the reptation mechanism is inversely proportional to its size.

When a DNA molecule is much longer than the average mesh spacing of the fibrous network, then a strong entanglement may be expected and the molecule migrates stretched nearly all the time. The tendency to the permanent stretching increases with the length of a molecule and even shorter molecules can be permanently stretched in high electric field strength. The separation selectivity under these conditions decreases to zero. The scheme of DNA migration in a network of pores of the separation matrix is shown in Figure 2.

**Figure 2** Schematic view of DNA migration regimes: (A) Ogston sieving; (B) biased reptation; and (C) reptation with permanent stretching.  $R_g$  – radius of hydrodynamic equivalent sphere of DNA coil;  $S$  – average mesh size.

The model of DNA electrophoretic migration explains the difficulties with separations of long DNA fragments (longer than few tens of kilobases). This effect can be overcome by using pulsed electric fields for the separation of the very long fragments. Besides the simplest pulsed field arrangement a number of two-dimensional electrode arrangements and pulse programs were developed and commercial instrumentation is now available for the separation of chromosomal DNA with the length in the range of megabases.

SGE is one of the analytical techniques most often used in molecular biology, forensic science, and biotechnology. The instrumentation typically consists of an electrolyte tank for the placement of the gel equipped with electrodes for connection of the power supply. The gels, mostly of polyacrylamide or agarose, can be prepared in the laboratory or purchased precast. In the case of polyacrylamide the pore size can be varied by selecting the total concentration of the monomer acrylamide taken for the polymerization (typically 3–20%, denoted as T) and the amount of the bisacrylamide cross-linker (typically 0.5–5%, denoted as C). The agarose gels are mostly prepared in the concentrations of 0.5–2%. The detection of the DNA bands in SGE is most often performed either using radiography with radiolabeled DNA fragments or, after staining with an intercalating dye (e.g., ethidium bromide), by observing visible fluorescence under a UV transilluminator.

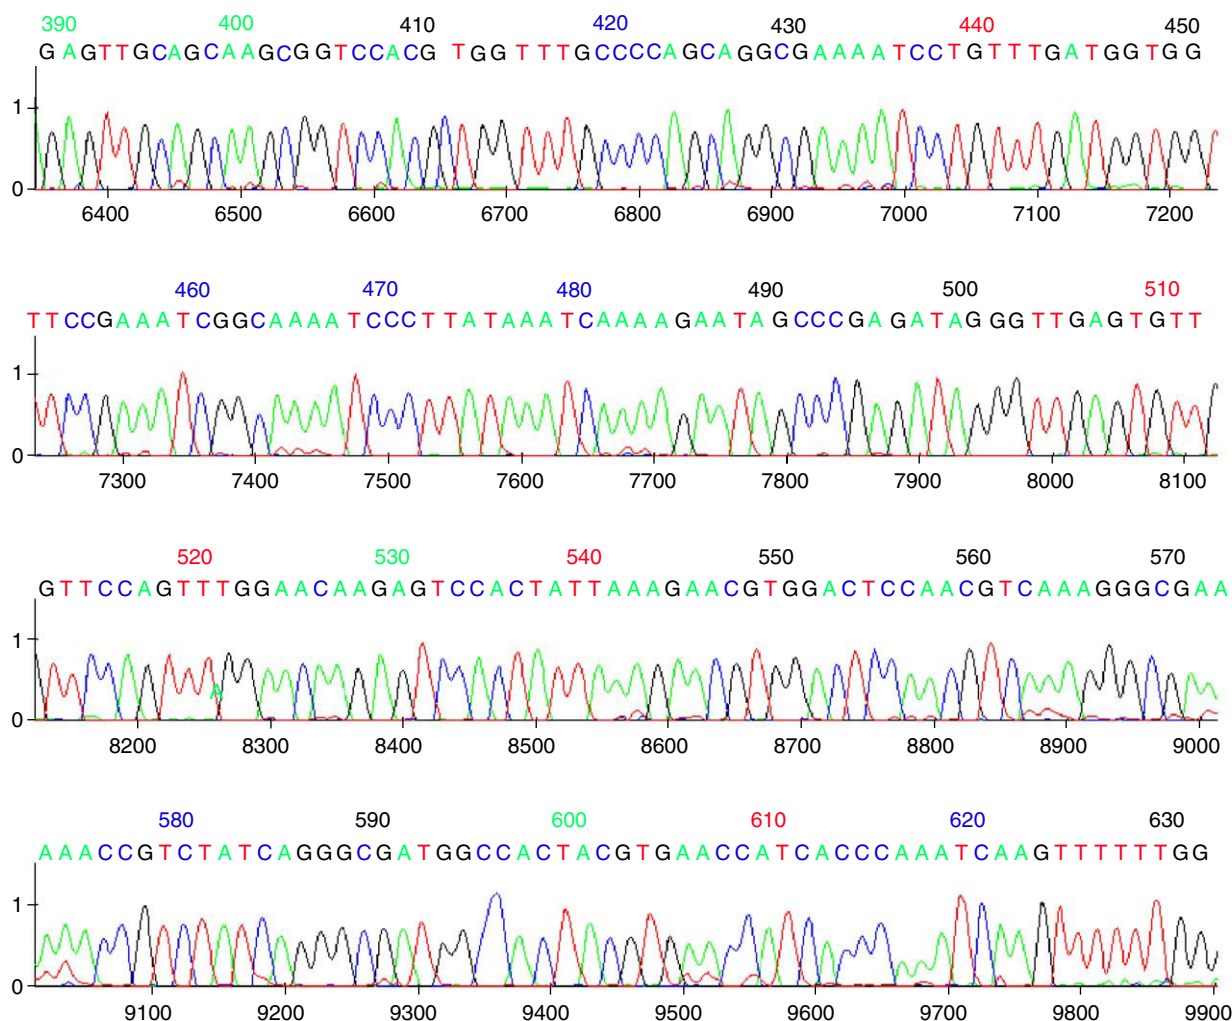

## Capillary Electrophoresis

The basic scheme of CE instrumentation is shown in Figure 3. The separation capillary is filled with the separation matrix (solution of hydrophilic linear polymers, e.g., linear polyacrylamide or its derivative) from a common pressurized matrix reservoir and is replaced after every analysis run. Besides the linear polymer the matrix contains an electrolyte buffer also (mostly good buffers at pH 8–10) to maintain constant ionic strength and pH. The samples are loaded from microtiter well plates by applying voltage for predefined periods of time. Finally, the separation voltage is applied via the electrode reservoirs at the ends of the capillary array. Fused silica capillaries with inner diameters of 50–100  $\mu\text{m}$  are typically used as the separation columns. The detection systems with direct data acquisition are based on LIF. The separation voltage ranges from 2 to 30 kV.

In analogy to SGE, where multiple samples can be separated in parallel, capillary array electrophoresis (CAE) systems were developed to enhance the

**Figure 3** Scheme of a capillary electrophoresis system.

**Figure 4** Typical record of a separation of DNA sequencing fragments. Four colors indicate four terminating nucleotides specifically labeled by four fluorescent tags. Thus, the individual bases are called and sequence determined (row of letters). The segment of the separation spectrum between 6400 and 9900 time points corresponds to the migration time 60–95 min. The numbers over the sequence are sizes of fragments in number of nucleotides or position of a nucleotide in the sequence.

throughput of genetic mapping and DNA sequencing. Present fully automated CAE systems operate up to 384 capillaries simultaneously.

## Separation Modes in Electrophoresis of Nucleic Acids

There are different modes of conducting the electrophoresis to achieve the required separation of DNA or RNA fragments. For example, the mutation detection or gene-polymorphism analysis can be based on restriction fragment length polymorphism (RFLP), length polymorphism of PCR amplified fragments (AFLP), single-strand conformation polymorphism (SSCP), heteroduplex analysis, DNA-DNA hybridization, or denaturing gradient gel electrophoresis (DGGE). Varieties of these techniques can be performed in both the slab gel and in the capillary formats. Besides using the network of pores of the separation (sieving) matrix, there are additional ways of influencing the resolution of nucleic acids. One of the most important factors is the use of denaturants and elevated temperature. Typically, the addition of urea (up to  $11\text{ mol l}^{-1}$ ) and/or formamide and elevation of temperature up to  $90^{\circ}\text{C}$  provides conditions for partial or complete denaturation of the DNA strands. While the use of native (no denaturant added) or partly denaturing conditions may be useful for the analysis of double-stranded DNA and/or sequence-dependent separation of the fragments of the same size, the highly denaturing conditions are required for the size-dependent separations such as DNA sequencing.

## DNA Sequencing

DNA sequencing was the most successful application of CE, both scientifically and commercially. Since the procedure relies on the capability to resolve fragments differing by a single nucleotide, the conditions providing the highest separation efficiency must be selected. Thus, relatively long separation distances (tens of centimeters) are used together with highly denaturing sieving matrices operated at elevated temperature. Such conditions prevent self-hybridization of the DNA, which could result in compression of the bands of the G- and C-rich DNA fragments. The sequencing read length well over 1000 bases is possible in a 1 h with the current capillary array sequencers. Fully automated instrumentation including LIF detection and sophisticated software for real-time base calling is commercially available. An example of the sequencing record is given in Figure 4.

## Analysis of DNA Fragment Length Polymorphism

One of the most frequent CE techniques of DNA diagnostics is the monitoring of a length polymorphism of fragments prepared by PCR amplification of a genomic DNA (AFLP) or enzymatic cleavage (RFLP). The mutations caused by deletions or insertions in a genome can be detected as zones of fragments with different sizes.

The RFLP method is used not only for the mutation detection but also as a basis for construction of restriction (or physical) maps of various genomes. Such maps can be used for the molecular identification of microorganisms. Similar application of the size-based separations in diagnostics is the analysis of tandem repeat polymorphism. High-resolution AFLP methodologies are developed for the sizing of repetitive DNA sequences that are arrayed as tandem repeat units in noncoding regions of a genome. The separation of the double-stranded DNA fragments in

**Figure 5** Typical record of an SSCP analysis. Detection of point mutation (substitution of thymine to cytosine) causing phenylketonuria in a heterozygote. Four completely dissociated DNA strands with different sequences (two couples of complementary strands with and without the point mutation) are resolved as four conformers in a native separation environment. The large peak represents a portion of undissociated double-stranded DNA.

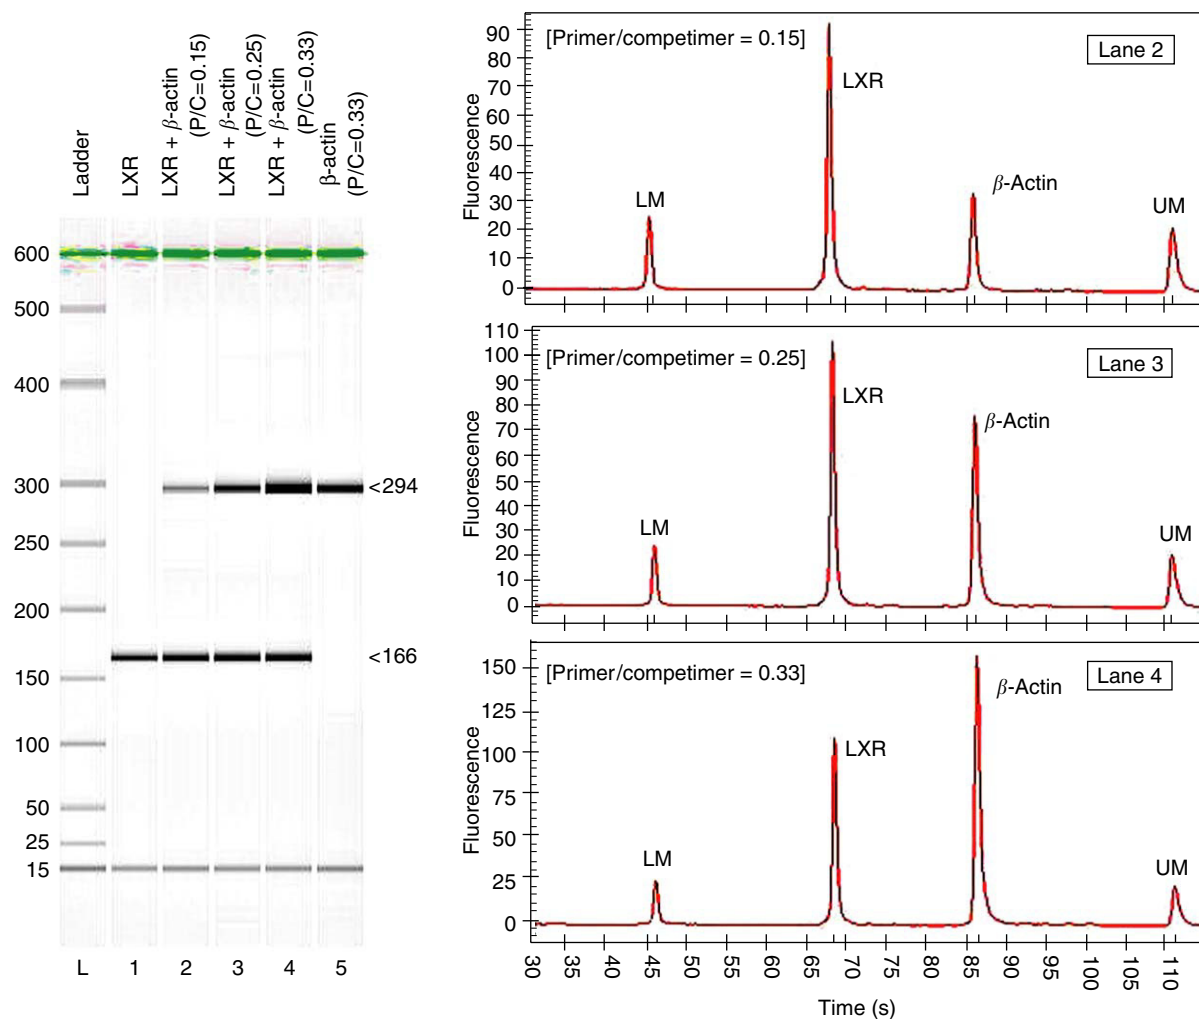

the size range of 50 bp to several kilobase pairs is performed under nondenaturing conditions.

## Single-Strand Conformation Polymorphism

SSCP is a popular technique for the screening of mutations or polymorphisms in short segments of DNA. Mutations are detected by monitoring of mobility shifts of individual DNA strands caused by their conformation changes. The main advantage of the SSCP technique is the ability to detect mutations (substitutions, small deletions, and insertions) at a variety of positions in DNA fragments with good

sensitivity. Even point mutations often give rise to conformation changes in nondenaturing environment and result in a mobility shift when molecules of the same number of nucleotides migrate in a sieving medium. Under nondenaturing conditions, the single DNA strands (ssDNA) adopt a folded structure, which is stabilized by intramolecular duplex between complementary regions and/or base stacking within each strand. Consequently, the folding and structural conformations depend not only on the presence of the mutations but also on the nucleotide sequence. Full theoretical understanding of all the factors affecting the three-dimensional folding of ssDNA fragments is still not available. Thus, the finding of the optimum conditions for SSCP analysis is highly

**Figure 6** On-chip analysis of the PCR amplification of LXR $\alpha$  gene from control human colon carcinoma cell line (CaCo-2) cells cDNA with 27 cycles. Lanes: 1, gene amplified with 5 pmol each of primers for LXR $\alpha$  gene; lanes 2–4, co-amplification of LXR $\alpha$  gene with  $\beta$ -actin at different ratios between primer and competitor; lane 5, amplification of  $\beta$ -actin gene with the primer-to-competitor being 0.42. The densitograms show the exact comparison of areas of LXR $\alpha$  gene and internal reference. LM, lower marker; UM, upper marker. empirical. In practice, the sample is denatured prior to analysis, the dissociated ssDNA fragments are applied to a native environment of a sieving medium and separated by electrophoresis. The denaturing can be accomplished chemically (e.g., by formamide) under highly alkaline conditions, physically at an elevated temperature, or by combination of both. The initial sample denaturing is accomplished by heating of the sample up to over 90°C for 1–5 min followed by immediate chilling on ice. An example of the application of the SSCP analysis performed in CE is shown in Figure 5.

## Separation Based on Partial Denaturing Conditions

Several variants of electrophoresis performed under partially denaturing conditions were developed in both the slab and capillary formats for detection of mutations and DNA variants. In contrast to the SSCP method, where the completely denatured ssDNA samples are analyzed in a nondenaturing sieving matrix, here the analyses proceed in a partially denaturing environment. Thus, the DNA strands are partially melted resulting in the stronger retardation of their migration through the sieving matrix. The separation selectivity of the method is based not only on the character and position of a mutation, but also on the denaturing parameters during the migration through a separation column. When the separation is performed using a gradient of the denaturant along the separation gel (DGGE), the migrating DNA bands individually reach a point of maximum retardation without the need for laborious searching for the optimum denaturant concentration. Besides the use of denaturants like urea and formamide, the precise control of the temperature during the run is important to achieve reproducible results. The capillary versions of the technique often keep the concentration of the denaturant constant and rely on the temperature control to optimize the separation, for example constant denaturant capillary electrophoresis.

## Electrophoresis on a Microfluidic Device

The development of the microfluidic systems for DNA analysis is a logical extension of the CE technology. The ‘chips’ manufactured from glass or plastic materials contain a number of microfabricated

channels and reservoirs integrating the sample loading and separation with postcolumn detection. The separation channels prepared by photolithography/wet chemical etching have typically semi-circular cross-section with the radius of  $\sim 50\ \mu\text{m}$  and depth  $\sim 20\ \mu\text{m}$ . The microfabricated systems in general use shorter separation distances than typical in capillaries resulting in further increase in the separation speed. Monitoring of the LIF signal at the end of the separation channel provides a means for detecting the very sharp zones migrating close to each other. Arrays of separation channels can be integrated with other components into a single device – the lab-on-a-chip concept. Thus, the miniaturized electrophoresis can be coupled with an automated online reaction chamber for DNA cleavage, PCR amplification, ligase chain reaction, etc. Several kits for specific applications in the DNA and RNA analysis with disposable separation chips are currently available commercially. An example of the analysis performed on a commercial microfabricated system is shown in Figure 6.

### Introduction

Spectroscopic methods can be divided into three main groups:

1. Electronic spectroscopy, including ultraviolet (UV) and visible absorption spectroscopy, fluorescence spectroscopy, circular dichroism (CD) and linear dichroism spectroscopy.
2. Vibrational spectroscopy, including infrared (IR) absorption spectroscopy, Raman spectroscopy, and vibrational circular dichroism spectroscopy.
3. Nuclear magnetic resonance (NMR) spectroscopy.

The basic principles and technical aspects of these methods are given elsewhere in this encyclopedia. Here, we discuss briefly the applications of CD, NMR, UV absorption, IR, and Raman spectroscopies to nucleic acid samples and the interpretation of such measurements. Other spectroscopic methods have been used much less to study nucleic acids during the last 5 years and we therefore omit them in this article.

The frequency domains where these three kinds of spectroscopic methods operate differ, thus determining the instances where these methods can be used and the concentrations (amounts) of the material to be measured. Electronic spectroscopies work with chromophores, usually of the nucleic acid bases or ligands bound to the nucleic acids. The chromophores absorb UV or visible light to make electronic spectroscopies relatively very sensitive compared to IR and NMR methods. Concentrations of the samples used for electronic spectroscopies can be very low (down to  $10 \mu\text{g ml}^{-1}$ ), which is important to avoid nucleic acid aggregations. Electronic spectroscopies essentially reflect orientation of the chromophores and hence the global nucleic acid conformation. Vibrational spectroscopies operate in the IR spectral region. They work with photon energies 1–2 orders of magnitude lesser than that used in electronic spectroscopies, which makes it necessary to use samples having concentrations of the order of milligrams per milliliter. IR methods reflect bond vibrations, i.e., they provide local information about the molecules of interest. The vibrations can be calculated quite reliably and the calculations can be compared to

experiments, thus contributing to the interpretation of the experimental data.

NMR spectroscopy measures transitions between the energy levels of nuclear spins in the radiofrequency range.  $^1\text{H}$ ,  $^{31}\text{P}$ ,  $^{13}\text{C}$ , and  $^{15}\text{N}$  are the most commonly used isotopes to study nucleic acids. A strong external magnetic field splits the energy levels of nuclear spins in proportion to the magnetogyric ratio  $\gamma$ . This constant, characteristic for each isotope, is generally very small causing low sensitivity of NMR even when the strongest available magnetic fields are applied. Some isotopes, e.g.,  $^{12}\text{C}$  (spin quantum number  $I = 0$ ) are inactive in NMR; others, e.g.,  $^{14}\text{N}$  ( $I = 1$ ), have undesirable NMR properties. The natural abundance is  $\sim 100\%$  for  $^1\text{H}$  (99.985%) and  $^{31}\text{P}$  (100%), but much lower in the cases of  $^{13}\text{C}$  (1.108%) and  $^{15}\text{N}$  (0.370%). This stimulates the preparation of nucleic acid samples enriched with  $^{13}\text{C}$  and/or  $^{15}\text{N}$  isotopes.

### UV Absorption Spectroscopy

Nucleic acid bases absorb UV light. Maximum absorption is observed  $\sim 260 \text{ nm}$ . The absorption can be used for basic nucleic acid sample characterization before it is subjected to a more sophisticated technique. Besides the band maximum  $\sim 260 \text{ nm}$ , nucleic acids display an absorption minimum at  $\sim 230 \text{ nm}$  and another maximum within  $170\text{--}200 \text{ nm}$ . Beyond  $300 \text{ nm}$ , nucleic acids absorb no light. Hence, a nonzero absorption signal beyond  $300 \text{ nm}$  indicates a loss of light caused by light scattering owing to nucleic acid aggregates or impurities. The  $A_{260}/A_{280}$  absorbance ratio should be  $\sim 1.8$  and the  $A_{260}/A_{230}$  ratio should be 2 or higher. Values of  $A_{260}/A_{280}$  lower than 1.8 or values of  $A_{260}/A_{230}$  lower than 2 indicate protein or other impurities.

UV absorption spectroscopy is further used to determine nucleic acid concentration. The average molecular weight of a nucleotide is 320 and  $50 \mu\text{g ml}^{-1}$  concentration of a random sequence DNA provides the  $A_{260}$  absorbance of  $\sim 1$  in a  $1 \text{ cm}$  pathlength cell. In practice, the absorption coefficient of DNA is precisely determined by enzymatic hydrolysis of DNA to monomers and calculation using the absorption coefficients of the monomers, or by measurement of thermally denatured DNA. The absorption of the denatured DNA sample is calculated on the basis of absorption coefficients of the constituent mono- and dinucleotides.

The absorption spectra of DNA and RNA are hypochromic, which means that the absorbance of

the polymeric or oligomeric chains is lower than that of the respective monomers. The absorbance of DNA and RNA decreases when going from single-stranded to double-stranded forms. Heating of nucleic acid solution causes a sharp UV absorption increase due to a partial loss of base stacking accompanying the strand dissociation. Melting point ( $T_m$ , midpoint of the transition) measurements have been widely used for the characterization of DNA samples of different origins to determine their (G + C) content having a taxonomic meaning, e.g., in bacteria. The sharpness (cooperativity) of the melting is an important characteristic of the DNA sample studied. It reflects internal heterogeneity of the primary structure of the DNA. Absorption spectroscopy also reflects conformational transitions, e.g., the B–Z transition, or transitions to tetraplex arrangements (see below).

## Circular Dichroism Spectroscopy

Circular dichroism (CD) arises owing to different absorptions by the analyzed nucleic acid sample of right-handed and left-handed circularly polarized light. Hence, it is a very small difference (of the order of thousandth) of two large numbers. This is one of the reasons why calculations mostly do not reproduce the experimental CD spectra of nucleic acids even qualitatively. Another reason is that the calculations are complex and the accurate dipolar and magnetic moments of the nucleic acid bases are not known. This is why CD is mostly used for empirical comparative studies of nucleic acids. On the other hand, the instrumentation is relatively cheap, the recording of spectra is easy and fast, and the samples can be titrated to change pH, salt concentration, or ligand concentration without any substantial problem. Moreover, CD spectroscopy is extremely sensitive to even slight changes in the mutual orientation of chromophores of nucleic acid bases. Therefore, it is the most frequently cited method in papers describing conformational transitions of nucleic acids and nucleic acid interactions.

Nucleic acids contain chiral nucleosides because of the C1' carbon atom of the sugar ring. However, the main contribution to CD follows from the asymmetric stacking of nucleosides into helical arrangements. These arrangements include, e.g., the B-form, A-form (a constitutive conformer of double-stranded RNA) that the DNA adopts upon dehydration, guanine tetraplexes, cytosine tetraplexes, and other conformers different from the common B-form DNA. CD spectra can not only be measured with nucleic acid solutions but also with films where the overall conformation can be assessed by X-ray diffraction. The CD spectra of the basic double helix types A and

**Figure 1** CD spectra of (left) B-DNA and A-DNA of d(GCGGCGACTGGTGAGTACGC) duplexed with its complementary sequence, and (right) A-RNA of the duplex with the same nucleotide sequence (with U instead of T). The NA samples were dissolved in 1 mmol l<sup>-1</sup> Na phosphate + 0.3 mmol l<sup>-1</sup> EDTA, pH 7. Trifluoroethanol was added to DNA up to 80% to induce the A-form. Spectra were taken at 0°C.

B are shown in **Figure 1**. The B-form CD spectrum is rather weak in the 200–300 nm spectral region and the amplitudes of the positive and negative bands are similar. The CD spectrum of the A-form is much stronger and is dominated by a positive band ~260 nm and a negative one at 210 nm. The A-form is adopted by RNA, and by many molecules of DNA in 80% aqueous ethanol.

Varying temperature, concentration of salt, pH, or other agents causes changes in the CD spectrum. The changes can be either noncooperative or cooperative (**Figure 2**). The noncooperative changes reflect gradual modifications of nucleic acid geometry within a single type of conformation, e.g., within B-DNA. In some situations, however, the molecule cooperatively switches from one type of geometry to a distinct geometry, e.g., from B to A. The cooperative changes can be identified by CD spectroscopy because the spectra are then linearly dependent, i.e., they can be reproduced by a linear combination of the spectra of the participating conformers. The cooperative changes are accompanied by isodichroic points, which are a consequence of intersections of the spectra of the two participating conformers. All the spectra recorded in the course of the transition should pass through the isodichroic point as well (**Figure 2**). Cooperative phenomena are characteristic by the S-shaped course of changes, monitored by the ellipticity at a selected wavelength (**Figure 2**, inset).

A synthetic DNA poly(dG–dC) · poly(dG–dC) is composed of a strictly alternating sequence G and C. It can be prepared *in vitro* by enzymatic methods. High salt or alcohol concentrations induce

**Figure 2** CD and (inset right) UV absorption spectra of poly(dG-dC) reflecting its B-Z transition induced by trifluoroethanol: (inset left) the transition monitored by  $\Delta\epsilon_{291}$ . The alcohol was added to the polynucleotide dissolved in 1 mmol l<sup>-1</sup> Na phosphate, 0.3 mmol l<sup>-1</sup> EDTA, pH 7 up to (thin black trace) 59.0, (dots) 62.5, (dashes) 63.5, and (thick red trace) 67.0%. The spectra were measured at 0°C.

a cooperative transition of poly(dG-dC) · poly(dG-dC) into the left-handed Z-DNA double helix. This transition was discovered by CD spectroscopy (Figure 2). Another synthetic polynucleotide poly(dA-dT) · poly(dA-dT) also undergoes salt- or alcohol-induced transitions. For some of the structures there is still no convincing conformational explanation. Alternating sequences of the purine and pyrimidine residues introduce a conformational polymorphism into DNA that can be studied by CD spectroscopy under a wide range of the solution conditions. In contrast, blocks of purine nucleotides bound to the complementary strand fix DNA in a single type of double-stranded conformation. For example, poly(dA) · poly(dT) is a heteronomous B-like duplex in which the strand of poly(dA) has a rather different conformation than the strand of poly(dT). The duplex of poly(dA) · poly(dT) cannot switch into the A-form at all, and only can become a part of a three-stranded conformation under favorable conditions. Also, strands of poly(dG) and poly(dC) form triplexes at slightly acid pH. Their duplex poly(dG) · poly(dC) adopts an unusual A-like conformation even in aqueous solution. It easily switches into the A-form in ethanol solutions. Most of these facts were first found using CD spectroscopy.

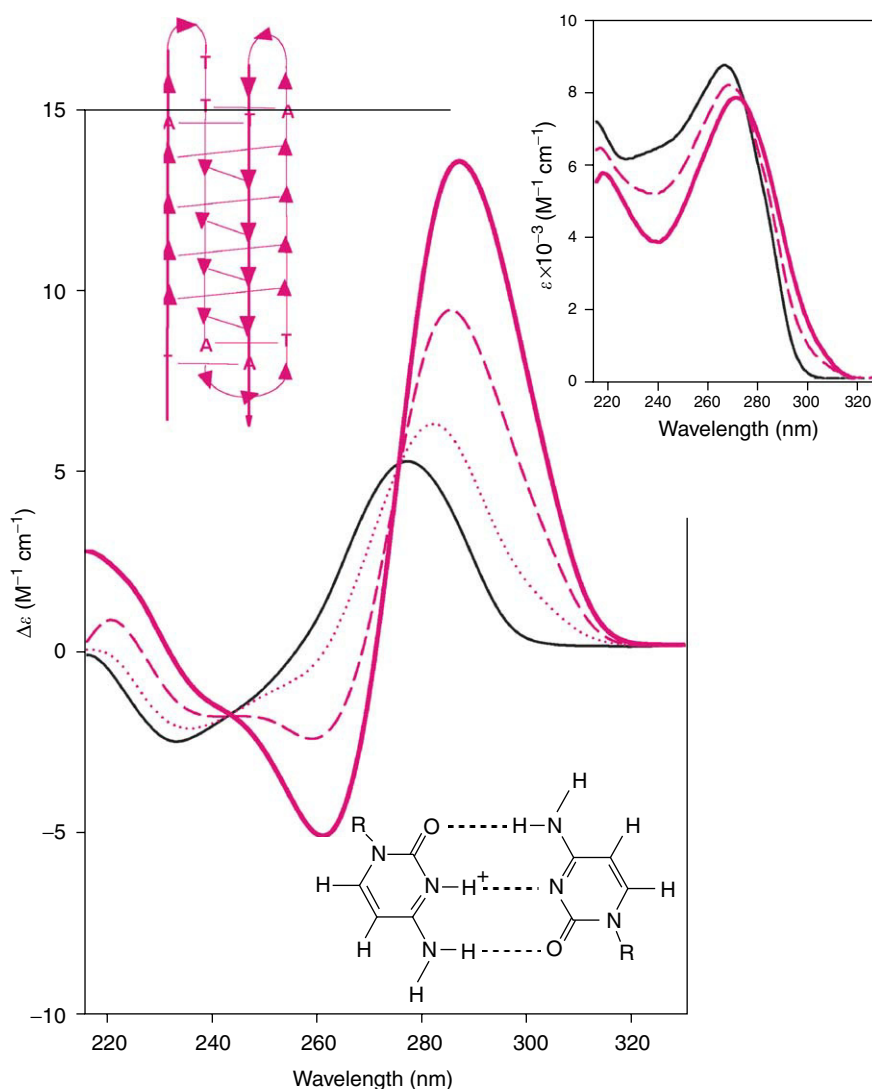

Cytosine-rich DNA strands associate into intercalated tetraplexes (i-tetraplexes). They consist of two parallel-stranded duplexes bound by hemiprotonated

C<sup>+</sup> · C<sup>+</sup> pairs that are mutually intercalated in anti-parallel direction (Figure 3). The intercalated tetraplexes can be formed by a single, two, or four molecules, but irrespective of the number of molecules involved the i-tetraplex always has the same strand topology and provides the same characteristic type of CD spectrum (Figure 3). Intercalated tetraplexes are mostly induced by slightly acid pH to make the cytosines hemiprotonated.

Guanine-rich DNA strands also associate into tetraplexes. Guanine tetraplexes are much more complex and difficult to work with because they can have various topologies (Figure 4). The type and concentration of cations, length and number of the guanine blocks in the molecule, and the primary structure of the loops determine the preferred type of guanine tetraplex topology. The various topologies provide different CD spectra (Figure 4). Transitions involving intermolecular tetraplexes are very slow (days).

(dG-dA)<sub>n</sub> strands associate into parallel-stranded homoduplexes whose CD spectra are very similar to the CD spectra of intermolecular guanine tetraplexes. The homoduplex formation is not restricted to the strictly alternating sequence of G and A, but a presence of guanine doublets or longer guanine runs leads to the formation of G-tetraplex.

CD spectroscopy was used in many instances to study conformational properties of DNA strands

**Figure 3** CD and (inset) UV absorption spectra reflecting the acid-induced transition of a DNA fragment d(TCCCCACCTTCCC-CACCCTCCCCACCTCCCCA) of a c-myc human oncogene into an i-tetraplex. Spectra were recorded at room temperature in Robinson–Britton buffer, pH (thin black trace) 9.2, (dots) 7.2, (dashes) 6.7, and (thick violet trace) 5.0. The triangles in the sketch stand for cytosines. They point in the 5' → 3' direction. The C<sup>+</sup>·C pair is shown at the bottom.

containing trinucleotide repeats whose expansion correlates with serious, mostly neurodegenerative human diseases. The strands include d(CAG)<sub>n</sub> and d(CTG)<sub>n</sub> (Huntington chorea and other diseases), d(GAC)<sub>n</sub> (multiple epiphyseal dysplasia), d(CCG)<sub>n</sub> and d(CGG)<sub>n</sub> (fragile X-chromosome syndrome), and d(GAA)<sub>n</sub> (Friedreich ataxia). CD spectroscopy contributed to a demonstration that all of the trinucleotide repeats generated stable intrastrand conformations, competing with the heteroduplex, with the complementary strand. Just these intrastrand structures are considered to be responsible for the repeat expansions. The strands of d(CAG)<sub>n</sub> fold into a stable hairpin, d(GAC)<sub>n</sub> form a hairpin, parallel homoduplex, and the left-handed Z-form, d(CCG)<sub>n</sub> generate a hairpin and two kinds of tetraplexes in

which C plays a dominant role, d(CGG)<sub>n</sub> form a hairpin and G-tetraplex for  $n < 5$ , and d(GAA)<sub>n</sub> form a homoduplex, ordered single strand, and a triplex in the presence of the complementary sequence. All of these unusual structures, arising as an alternative to classical DNA heteroduplex, yield characteristic CD spectra. Thus, CD spectroscopy can easily monitor the formation and the conditions of the stability of these structures.

## IR and Raman Spectroscopy

IR spectra can be obtained from solutions, gels, fibers, or films as well as crystals of nucleic acids. This is an important advantage because crystal conformations of DNA correspond to conformations that DNA

**Figure 4** CD spectra reflecting the formation of (left)  $\text{K}^+$ -induced parallel-stranded tetramolecular tetraplex of  $\text{G}_4$  and (right)  $\text{Na}^+$ -induced antiparallel bimolecular tetraplex of  $\text{G}_4\text{T}_4\text{G}_4$ . Both oligonucleotides were dissolved in  $1 \text{ mmol l}^{-1}$  Na phosphate +  $0.3 \text{ mmol l}^{-1}$  EDTA, pH 7, and thermally denatured before starting measurements. CD spectra were measured at room temperature (left): (thin black trace) immediately and (from dots to thick cyan line) 10', 3.5 and 24 h after adding  $10 \text{ mmol l}^{-1}$  K phosphate, pH 7; (right): (from the thin black to the thick green line) 1, 10, 100  $\text{mmol l}^{-1}$  Na phosphate, and +  $0.5 \text{ mol l}^{-1}$  NaCl, pH 7. The triangles in the sketches stand for guanines and point in the  $5' \rightarrow 3'$  direction. The G-tetrad is shown in the middle.

adopts in concentrated aqueous alcohols rather than dilute aqueous solutions. IR spectroscopy puts no limits on the size of the molecules. It can be used with high molecular weight native molecules of DNA as well as short oligonucleotides. Furthermore, it is a nondestructive method. The samples can be used for other purposes after the IR spectroscopic measurements.

The use of IR spectroscopy is based on the existence of marker bands in the spectral region between

$1800$  and  $700 \text{ cm}^{-1}$ , which are sensitive to nucleic acid conformation. The marker bands arise from vibrations in various parts of the molecule. Stretching double bond in plane vibrations of the bases provide bands within  $1800\text{--}1500 \text{ cm}^{-1}$ , sugar-base interactions (depending on the glycosidic torsion angle) are reflected within  $1500\text{--}1250 \text{ cm}^{-1}$ . Phosphate and sugar vibrations provide bands within  $1250\text{--}1000 \text{ cm}^{-1}$ , and the phosphodiester bonds vibrate below  $1000 \text{ cm}^{-1}$ . Solvent  $\text{H}_2\text{O}$  makes it

difficult to obtain data  $\sim 1600$  and below  $1000\text{ cm}^{-1}$ . This is why  $\text{D}_2\text{O}$  is used instead of  $\text{H}_2\text{O}$  in many IR spectroscopy studies of nucleic acids.

Photons are scattered by molecules and lose energy during the scattering process. The lost energy corresponds to the vibrational energy of the molecule. Hence, a Raman spectrum fingerprints vibrational states of the molecule that depend on its conformation and interactions. Raman spectroscopy complements IR spectroscopy. The major advantage of Raman spectroscopy lies in a very weak signal of water, whereas the  $\text{H}_2\text{O}$  signal is strong in the IR spectra and masks the signal of the nucleic acid dissolved in the water solution. Raman spectroscopy shares the advantage of IR spectroscopy to be able to work with crystals, solutions, gels, fibers, as well as amorphous solids. Combination of the X-ray data with Raman studies of the corresponding crystals permitted the identification of several spectral bands (i.e., their frequencies and intensities) that are characteristic, for example, including nucleoside sugar pucker (C3'-endo or C2'-endo) or orientation around the glycosidic bond (*syn* or *anti*). These spectral lines are frequently well separated from one another to detect two or more conformers in the same molecule. Overlapping bands should be deconvoluted.

## NMR Spectroscopy

NMR spectroscopy belongs to the group of radio-frequency spectroscopic techniques. Energy levels of atomic nuclei with nonzero spin quantum number  $I$  are split by the presence of a strong magnetic field  $B_0$  in proportion to their magnetogyric ratios  $\gamma$ . The energy difference  $\Delta E = h\gamma B_0/2\pi$  ( $h$  – Planck constant), and consequently the difference  $\Delta n$  in Boltzman populations of individual energy levels are very small. Typically,  $\Delta E \sim 10^{-25}$ – $10^{-27}$  J and  $\Delta n \sim 10^{-5}$ – $10^{-7}$ . As a result, NMR spectroscopy is a highly insensitive technique requiring very high magnetic fields (11.7–21.4 T) and relatively high concentration of samples ( $c \sim 0.5$ – $1\text{ mmol l}^{-1}$ , vol.  $\sim 200$ – $500\text{ }\mu\text{l}$ ) when studying DNA and RNA oligonucleotides. Resonance frequencies corresponding to  $\Delta E = h\nu$  depend on  $\gamma$  and  $B_0$ . For example, at the  $B_0 = 11.7\text{ T}$  the most sensitive natural abundant isotope  $^1\text{H}$  resonates at 500 MHz while the resonance frequencies for  $^{13}\text{C}$ ,  $^{15}\text{N}$ , and  $^{31}\text{P}$  are 125.8, 50.7, and 202.2 MHz, respectively. Due to a large difference of resonance frequencies the high-resolution spectra of individual isotopes have to be measured separately. The differences in the electronic environment of atomic nuclei in different parts of the same molecule are slightly modifying the resonance frequencies and give rise to chemical shift dispersion

of the observed signals. The chemical shift ranges for  $^1\text{H}$ ,  $^{13}\text{C}$ ,  $^{15}\text{N}$ , and  $^{31}\text{P}$  isotopes in nucleic acids are  $\sim 1$ – $16$ ,  $10$ – $160$ ,  $70$ – $230$ , and  $0$ – $5$  ppm on their respective chemical shift scales. As standards for the chemical shift referencing, the signals of  $^1\text{H}$  and  $^{13}\text{C}$  of tetramethylsilane,  $^{15}\text{N}$  of liquid ammonia, and  $^{31}\text{P}$  of trimethylphosphate are typically used.

High-resolution NMR spectroscopy of samples in liquid state provides a wealth of structural information since the linewidth of the resonance signals is much smaller ( $\sim 10^{-1}$ – $10^1$  Hz) than their chemical shift dispersion. For example, the chemical shifts of  $^1\text{H}$ ,  $^{13}\text{C}$ ,  $^{15}\text{N}$ , and  $^{31}\text{P}$  isotopes in nucleic acids at  $B_0 = 11.7\text{ T}$  ( $\nu(^1\text{H}) \sim 500\text{ MHz}$ ) cover the frequency ranges of 7.5, 19, 8.2, and 1.1 kHz, respectively. In addition, a hyperfine splitting and multiplet structure of resonance signals can be observed as a result of electron-mediated nuclear spin–spin scalar interactions. Both chemical shifts and scalar interactions reflect the chemical environment and provide a wealth of structure-related data. Since specific information about the individual atoms is available, NMR data can be successfully used to calculate a three-dimensional structure of RNA and DNA molecules. Fuelled by methodological developments during the past 10 years, NMR became an indispensable tool for structure elucidation of nucleic acids. At present (April 2003), almost 600 NMR structures of nucleic acids and/or protein/nucleic acid complexes can be found in the PDB database.

The process of DNA/RNA structure determination can be divided in several steps. First, a sufficient amount of the sample has to be prepared. Although basic structural information can be obtained using solely  $^1\text{H}$  NMR spectroscopy, high-resolution structure determination of larger oligonucleotides requires isotope labeling by  $^{13}\text{C}$  and/or  $^{15}\text{N}$ . For preparation of samples with natural level of  $^{13}\text{C}$  and  $^{15}\text{N}$  isotopes, the chemical synthesis of DNAs by the phosphoramidite method and the enzymatic synthesis of RNAs using T7-polymerase are typically used. For isotope labeling with high levels of enrichments ( $\sim 99\%$ ), enzymatic synthesis both for RNAs and DNAs is a method of choice. In the next step, the signals in NMR spectrum are assigned to individual atoms. A vast number of homonuclear and heteronuclear NMR techniques have been designed to assist the assignments procedure. The base pairing is established by measuring the NMR spectra of exchangeable protons in  $\text{H}_2\text{O}$  solution. The observation of imino and amino signals is indicative for base pairing and hydrogen bond formation. Otherwise, these protons exchange rapidly with the solvent and their signals cannot be observed. Two-dimensional nuclear Overhauser effect (NOE) spectroscopy,

which identifies neighboring protons in the vicinity of  $\sim 5$  Å, enables the detection of both intraresidual and sequential imino-imino and imino-amino connectivities and the determination of the specific type of base pairing (Watson-Crick, non-Watson-Crick, or Hoogsteen). Then, NOE contacts of the imino and amino protons with the base (H6/H8, H5(methyl), adenine H2) and H1' protons are examined to obtain partial assignments. Assignments of other nonexchangeable protons are obtained from spectra measured in deuterated water mostly through H6/8-H1' and H6/8-H2'/2'' sequential NOE connectivities (Figure 5). The spin systems of sugar (H1', H2'/H2'', H3', H4', H5'/H5'') and pyrimidine bases (H5, H6) are identified using two-dimensional correlation spectroscopy or total correlation spectroscopy based on the existing network of spin-spin scalar interactions. Due to the increasing overlap of signals, the assignment of protons described above gets more complicated for larger systems with more than 20–30 nucleotides. The isotope labeling in combination with multidimensional data acquisition allows one to reduce the overlap observed in proton NMR spectra by using the advantage of much larger chemical shift dispersion of  $^{13}\text{C}$  and  $^{15}\text{N}$  isotopes. A large number of heteronuclear two- and three-dimensional techniques have been proposed to aid this process.

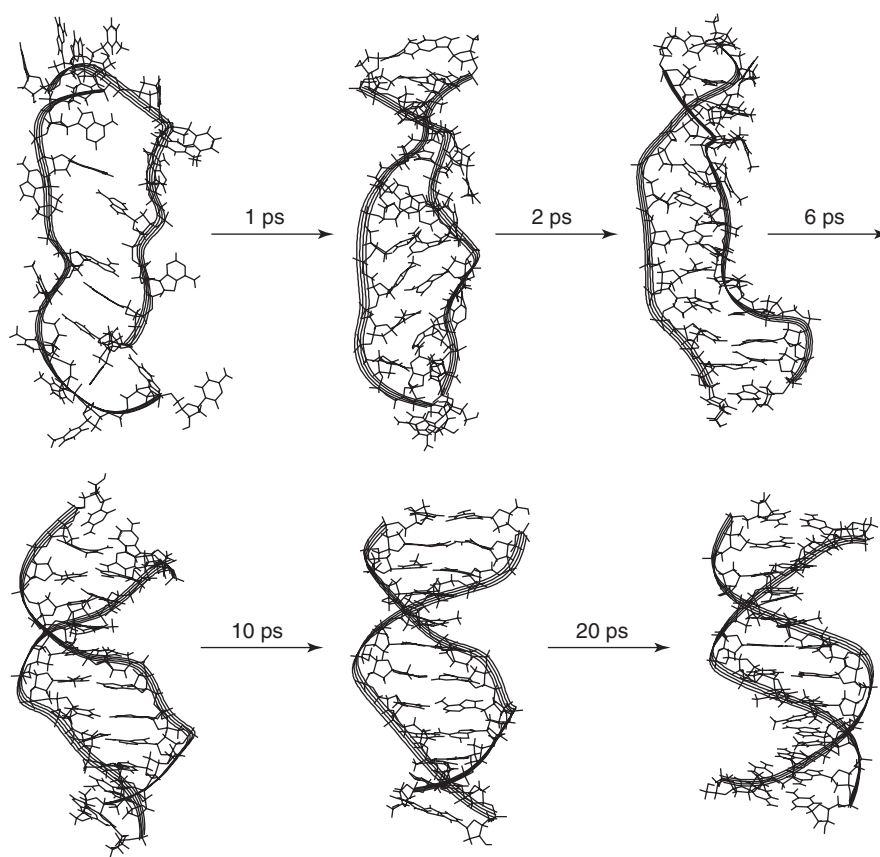

**Figure 5** Sequential NOE connectivities in DNA between sugar H1' and base protons (H6 in pyrimidines and H8 in purines). The intra- and inter-residual connectivities are marked in red and blue, respectively.

After the signals have been assigned the structural parameters are extracted. The basic information is obtained from the chemical shifts. Their values depend on the electron densities around the nuclei and are affected both by intra- and inter-residual interactions. The proton chemical shifts are strongly influenced by stacking interactions and their changes can be readily used to follow conformational changes such as melting of the elements of secondary and tertiary structures. The phosphorus chemical shifts depend on the conformation of the sugar-phosphate backbone. For example, their values display characteristic changes during B<sub>I</sub>-B<sub>II</sub>, B-Z, and B-X transitions. Quantitative structure-related information is obtained from the measurements of NOE intensities in multidimensional spectra. NOE reflects the dipole-dipole interaction between two nuclei and its intensity is indirectly proportional to the sixth power of the internuclear distance ( $\sim r^{-6}$ ). Distances up to 5 Å are determined with sufficiently high precision and accuracy. A number of torsion angles along the sugar-phosphate backbone, as well as the glycosidic torsion angle  $\chi$ , can be estimated from the values of homonuclear ( $^1\text{H}$ - $^1\text{H}$ ) and heteronuclear ( $^1\text{H}$ - $^{13}\text{C}$ ,  $^1\text{H}$ - $^{31}\text{P}$ ,  $^{13}\text{C}$ - $^{31}\text{P}$ ) three-bond scalar couplings using suitably parametrized Karplus equations. Proton-proton scalar interactions H1'-H2', H1'-H2'', H1'-H3', H2'-H3', and H2''-H3' are used to obtain information about the sugar pucker conformation both in  $\beta$ -d-deoxyribose (DNA) and  $\beta$ -d-ribose (RNA) and to estimate the populations of N- and S-type conformers.

The distances and the torsion angles extracted from NMR spectra as described above, together with the basic information about the primary sequence, bond length, and bond angles are subsequently used to calculate a three-dimensional structure of nucleic acids by molecular dynamics. First, the distance geometry approach or molecular dynamics in torsion space is applied to obtain the basic fold, which fulfills the experimental data used as restraints. Calculations are repeated for a set of completely randomized structures (Figure 6). In the next step, based on the energy and violations of the input restraints, a subset of converging structures is selected and subsequently refined using more sophisticated restrained molecular dynamics protocols.

Structure determination of nucleic acids faces several problems, which stem mostly from low proton density, lack of long-range restraints due to an elongated shape of majority structures, and a small number of NOE restraints between the distant elements of secondary structure. These difficulties can be circumvented by applying recently introduced technology for obtaining additional structural

**Figure 6** Folding of a DNA double helix during the 20 ps molecular dynamics refinement using NMR restraints.

**Figure 7** Three-dimensional structure of DNA hairpin d(GCGAAGC) determined using NMR data obtained on a  $^{13}\text{C}$ - and  $^{15}\text{N}$ -labeled molecule. NOE, dihedral, and RDC restraints were applied to refine the structure using molecular dynamics simulations using AMBER 7.0 software package.

restraints using a small degree of molecular alignment with the magnetic field. Newly introduced methodology provides the direct way to acquire the lacking long-range restraints. A weak alignment of biological macromolecules is easily obtained in solutions of bicells, filamentous phages, or other compounds. In such media, dipole–dipole and quadrupolar interactions, as well as chemical shift anisotropy, normally averaged out by an isotropic

tumbling, give rise to observable changes in the NMR spectra. Residual dipolar couplings or changes in the chemical shifts supply information about the mutual orientation of remote parts of the molecules. For example, in nucleic acids, mutual position of distant ends of double-helical DNA structures or of individual domains in RNA molecules can be accurately defined. To name just two from a large number of recently published results, high-resolution

structures of the Drew–Dickerson dodecamer (dCGCGAATTCGCG)<sub>2</sub> and the DNA hairpin d(GCGAAGC) (Figure 7) have been determined with very high precision using the isotope labeling and the alignment methodology.

Current state-of-the-art NMR technology allows studying the fragments of nucleic acids of the size up to 70 nucleotides. For molecules with more than 40 residues, the uniform <sup>13</sup>C, <sup>15</sup>N isotope labeling, which, in general, is more complicated than in proteins, has to be complemented also by residue- or site-specific labeling. For oligonucleotides with more than 50 residues partial deuteration seems to be mandatory. Despite these obstacles, the recent improvement of labeling strategies, development of new and more sophisticated NMR methods, and progress in measurements and applications of residual dipolar couplings for structure refinement have paved the way to improve the accuracy and precision of structures obtained by NMR and to study systems with larger number of nucleotides.

### Introduction

DNA and RNA are complex biomacromolecules whose structures and interactions are intensively studied mainly in relation to their biological roles. The main interest of scientists is not oriented to the determination of nucleic acids in biological materials but to analysis of their nucleotide sequence, secondary and tertiary structures, specific interactions with proteins, etc. A number of diverse techniques are necessary such as absorption spectroscopy, chromatography, gel electrophoresis, and radioactive and nonradioactive labeling, which can be found in almost every nucleic acid laboratory, while other less universal techniques are applied in relation to the specific aims of the given laboratory. Electrochemical methods briefly reviewed in this article belong to the latter category. They can be extremely useful for a number of purposes, such as determination of traces

of proteins, RNA and single-stranded DNA (ssDNA) in double-stranded DNA (dsDNA) samples, detection of DNA damage and nucleotide sequencing by DNA hybridization, etc. They do not require expensive equipment and give a good sensitivity, which, in some cases, can reach levels comparable to those of radioactive tracing. In recent years, electrochemistry has gained importance in the development of the DNA sensors.

Electroactivity of nucleic acids was discovered more than 40 years ago. Nucleic acid bases undergo redox processes at electrodes and in long-chain DNA molecules the resulting electrochemical signals can be significantly influenced by their ordered higher structures. This makes it possible to study structural transitions in nucleic acids and to detect minor damages to the DNA double helix. Interactions of nucleic acids with electroactive substances can be manifested by changes both in the signals of the given electroactive substance and in the signals of the nucleic acid. In addition to the natural electroactivity of nucleic acids, noncovalently (DNA groove binders and intercalators) and covalently binding electroactive

structures of the Drew–Dickerson dodecamer (dCGCGAATTCGCG)<sub>2</sub> and the DNA hairpin d(GCGAAGC) (Figure 7) have been determined with very high precision using the isotope labeling and the alignment methodology.

Current state-of-the-art NMR technology allows studying the fragments of nucleic acids of the size up to 70 nucleotides. For molecules with more than 40 residues, the uniform <sup>13</sup>C, <sup>15</sup>N isotope labeling, which, in general, is more complicated than in proteins, has to be complemented also by residue- or site-specific labeling. For oligonucleotides with more than 50 residues partial deuteration seems to be mandatory. Despite these obstacles, the recent improvement of labeling strategies, development of new and more sophisticated NMR methods, and progress in measurements and applications of residual dipolar couplings for structure refinement have paved the way to improve the accuracy and precision of structures obtained by NMR and to study systems with larger number of nucleotides.

### Introduction

DNA and RNA are complex biomacromolecules whose structures and interactions are intensively studied mainly in relation to their biological roles. The main interest of scientists is not oriented to the determination of nucleic acids in biological materials but to analysis of their nucleotide sequence, secondary and tertiary structures, specific interactions with proteins, etc. A number of diverse techniques are necessary such as absorption spectroscopy, chromatography, gel electrophoresis, and radioactive and nonradioactive labeling, which can be found in almost every nucleic acid laboratory, while other less universal techniques are applied in relation to the specific aims of the given laboratory. Electrochemical methods briefly reviewed in this article belong to the latter category. They can be extremely useful for a number of purposes, such as determination of traces

of proteins, RNA and single-stranded DNA (ssDNA) in double-stranded DNA (dsDNA) samples, detection of DNA damage and nucleotide sequencing by DNA hybridization, etc. They do not require expensive equipment and give a good sensitivity, which, in some cases, can reach levels comparable to those of radioactive tracing. In recent years, electrochemistry has gained importance in the development of the DNA sensors.

Electroactivity of nucleic acids was discovered more than 40 years ago. Nucleic acid bases undergo redox processes at electrodes and in long-chain DNA molecules the resulting electrochemical signals can be significantly influenced by their ordered higher structures. This makes it possible to study structural transitions in nucleic acids and to detect minor damages to the DNA double helix. Interactions of nucleic acids with electroactive substances can be manifested by changes both in the signals of the given electroactive substance and in the signals of the nucleic acid. In addition to the natural electroactivity of nucleic acids, noncovalently (DNA groove binders and intercalators) and covalently binding electroactive

markers can be introduced into DNA and used in their analysis. In the last decade, the above principles were intensively utilized in the development of sensors for DNA damage and hybridization.

### Working (Indicator) Electrodes

Nucleic acids have been analyzed primarily with liquid mercury and solid carbon electrodes; some work has also been done with other electrodes such as platinum, gold, indium tin oxide (ITO), silver, copper, as well as solid amalgam electrodes. The potential windows in which most solid electrodes can be used is shifted by  $\sim 1$  V to more positive values when comparing with mercury and some solid amalgam electrodes (operating between 0 and  $-2$  V against the saturated calomel electrode at neutral and alkaline pHs). Therefore, solid (not containing mercury) electrodes are better suited for studying nucleic acid oxidation, while mercury electrodes (mainly hanging mercury drop electrode (HMDE) and solid amalgam electrodes) are better for investigating nucleic acid reduction. Moreover, the atomically smooth and highly reproducible surfaces of liquid mercury are

well suited for a.c. impedance measurements, providing information about DNA interfacial properties.

## Redox Groups in Nucleic Acids

Among nucleic acid components purine and pyrimidine bases are electroactive; deoxyribose and ribose in nucleosides and nucleotides as well as phosphate groups are inactive at most types of electrodes.

### Reduction and Oxidation of Bases

Primary reduction sites of adenine, cytosine, and guanine and oxidation sites of adenine and guanine are shown in the Watson–Crick base pairing scheme (Figure 1A).

The reduction sites of adenine and cytosine are involved in the hydrogen bond system and hidden in the double helix interior. Neither the reduction site of guanine nor the oxidation sites of adenine and guanine are involved in this system. Signals caused by reduction of adenine and cytosine are strongly influenced by the DNA secondary structure in agreement with the location of the respective reduction sites.

**Figure 1** Reduction and oxidation of single-stranded and double-stranded nucleic acids at electrodes. (A) Schematic representation of Watson–Crick base pairs and electroactive groups. Primary reduction and oxidation sites at mercury (rectangles) and carbon electrodes (circles) are shown. (B) Cyclic voltammograms of synthetic polynucleotides ( $100 \mu\text{g ml}^{-1}$ ) measured at the hanging mercury drop electrode (HMDE). <sup>b</sup>Sparingly soluble compound with the electrode mercury +, is produced, –, is not produced. In CSV, the detection limit of nucleic acid bases is  $\sim 10^{-9} \text{ mol l}^{-1}$  for purines and  $10^{-8} \text{ mol l}^{-1}$  for pyrimidines with the exception of 5-methyl cytosine and 5-hydroxymethyl cytosine, which can be determined only at higher concentrations. Sparingly soluble compounds of copper(I) with bases accumulate at electrodes. Liquid and solid copper amalgam electrodes can be used to determine purine bases at concentrations down to  $10^{-11} \text{ mol l}^{-1}$  (Jelen *et al.* (2002) Determination of picogram quantities of DNA by stripping voltammetry with solid copper amalgam or mercury electrodes in the presence of copper. *Analytical Chemistry* 74: 4788–4793 and references therein).

The small difference in the intensities of the ds- and ssDNA oxidation signals (obtained with carbon electrodes) was explained by the difference in flexibility of these two DNA forms rather than by the direct influence of the secondary structure.

### Compounds with the Electrode Mercury

Groups responsible for the formation of the mercury compounds may involve exocyclic and ring nitrogens depending on the nature of the base and experimental conditions. At alkaline pH the mercury binding site of adenine is the 6-aminogroup. Purine nucleosides behave similarly to their parent bases while the pyrimidine analogs are inactive due to substitution of the pyrimidine ring by a sugar residue at N1, which is involved in the binding of mercury.

### Analysis of Nucleic Acid Components

Adenine and guanine can be analyzed at a carbon electrode and adenine and cytosine at a mercury electrode by differential pulse voltammetry (polarography) (DPV, DPP) at micromolar concentrations. Determination of bases by cathodic stripping voltammetry (CSV) (see above) gives substantially better sensitivities. In addition to the nucleic acid

components, a large number of purine and pyrimidine derivatives have been investigated (Table 1).

Most of them form sparingly soluble compounds with the electrode mercury and can be determined by CSV at nanomolar concentrations. At these concentrations 100-fold excess of various substances including proteins and nucleic acids have little influence on the CSV peak height of the nucleic acid bases. This makes it possible to analyze mixtures of bases with nucleic acids, the analysis of which by optical methods without separation is impossible. Sensitivity of the determination of purine and pyrimidine bases can be increased by one to three orders of magnitude if the analysis is performed in alkaline media in the presence of copper ions or at solid copper amalgam electrodes.

### Analysis of Nucleic Acids

Various electrochemical methods have been applied for the analysis of nucleic acids, including DPP and DPV, cyclic voltammetry, a.c. voltammetry, and constant current chronopotentiometry, which are particularly useful. Guanine (G) and adenine (A) residues in DNA and RNA molecules are oxidized at carbon electrodes; however, their voltammetric peaks are poorly developed, providing insufficient sensitivity in

the DNA analysis. Recent application of sophisticated baseline correction techniques, mainly in connection with constant current chronopotentiometry, produced well-developed oxidation peaks of DNA and RNA at carbon electrodes (Figures 1C and 1D). Cytosine (C) and A residues in ssDNA and RNA are reduced at mercury electrodes, producing reduction signals close to  $-1.4$  V at acid and neutral pH. In cyclic modes, G produces an anodic signal close to  $-0.3$  V, which is due to oxidation of the G reduction product forming at the highly negative potentials of the background discharge (Figure 1).

### Influence of DNA Structure

The primary reduction sites of A and C form a part of the Watson–Crick hydrogen bonding system (Figure 1A), being located in the interior of the DNA double helix. Reduction signals of A and C are strongly influenced by DNA structure; the reduction peak of single-stranded (denatured) calf thymus DNA can be almost 100-times higher than that of the parental duplex (native) calf thymus DNA. Similarly, the non-Faradaic signals of DNA produced by a.c. voltammetry are highly sensitive to changes in DNA structure. These signals can provide information about accessibility of bases for the interaction with the electrode. Such a strong influence of DNA structure on electrochemical signals makes the mercury electrodes well suited for detection of local conformational changes and DNA structural transitions. Mercury electrodes sensitively reflect single-strand interruptions in linear and circular DNA molecules, as well as superhelix density-dependent structural transitions in DNA. Mercury electrodes are able to discriminate between RNA and DNA making possible the most sensitive label-free determination of traces of RNA in a large excess of DNA. Oxidation peaks of A and G at carbon electrodes and anodic signal of G at mercury electrodes are less sensitive to changes in DNA structure.

### Changes in DNA Structure at the Electrode Surface

At a wide range of potentials, dsDNA is adsorbed at the electrode without any detectable unwinding. However, at certain potentials relatively slow unwinding of dsDNA at mercury was observed. No such changes were observed in covalently closed circular DNAs. At neutral and weakly alkaline pHs prolonged contact of dsDNA with the surface of the mercury electrode charged to potentials around  $-1.2$  V results in profound changes in the DNA electrochemical responses. These changes are caused by the opening of the DNA double helix at the electrode surface. They are relatively slow (tens to

hundreds of seconds) and can be observed by various techniques if dsDNA is exposed to potentials close to  $-1.2$  V for a sufficient period of time. To avoid these changes methods working with small voltage excursions during the (DME) drop lifetime should be applied. In experiments with HMDE the surface changes in the DNA structure can be minimized by proper voltage scanning. A d.c. field induced denaturation of short dsDNA molecules was recently detected by surface plasmon resonance at gold electrodes.

## Electroactive Labels and Chemical Modification of Nucleic Acids

Reduction and oxidation of natural nucleic acids is electrochemically irreversible and occurs at highly positive or highly negative potentials. To increase the sensitivity of the analysis electroactive markers were introduced into DNA which either undergo reversible electrode reaction at less extreme potentials or produce high electron yield catalytic signals. Here, only a few examples of nucleic acid electroactive labels will be mentioned, and the electrochemical properties of peptide nucleic acid (PNA) will be summarized.

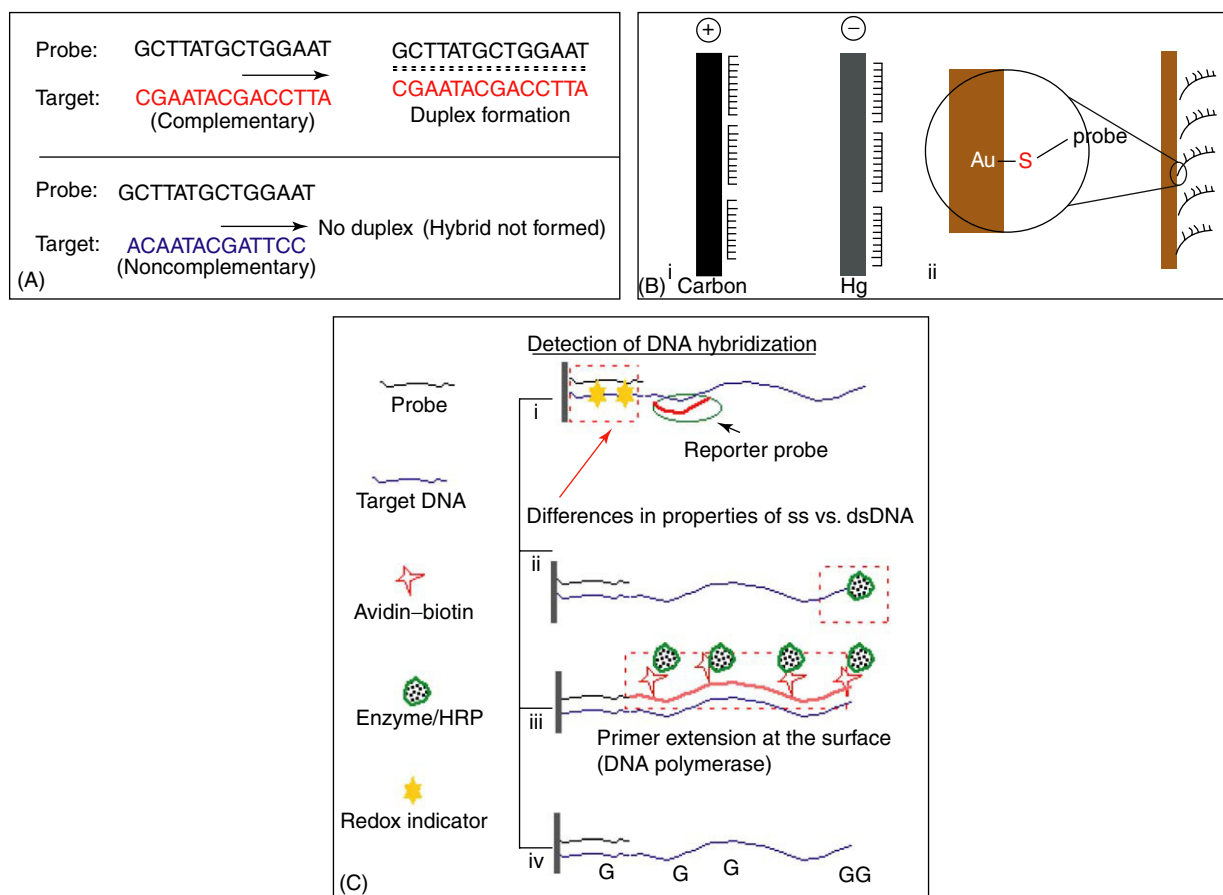

### Noncovalently Bound Labels

Molecules and ions interact with DNA in three basic ways: (1) nonspecific electrostatic binding along the exterior of the DNA double helix; (2) groove binding involving direct interaction of the bound molecule with the edges of base pairs in the DNA grooves; (3) intercalation of planar aromatic ring systems between DNA base pairs. A large number of the substances capable of interacting with DNA, particularly intercalators and groove binders, are electroactive.

Intercalating and DNA surface binding of metal chelates were studied by voltammetric methods. On addition of dsDNA to intercalators (e.g.,  $\text{Co(phen)}^{3+}$ ) a shift to more positive values was observed (suggesting stronger hydrophobic interactions) while with electrostatic binders such as  $\text{tris(2,2'-bipyridine)-osmium(II)}$ , the cathodic and anodic peak potentials shifted to more negative values. Electrogenated chemiluminescence as well as DNA redox active intercalators and groove binders were utilized in the development of the DNA hybridization sensors (see Figure 2 and below).

### Chemically Modified Nucleic Acids

Osmium tetroxide complexes were probably the first electroactive labels covalently bound to DNA. Some of these complexes, such as those with osmium tetroxide, and 2,2'-bipyridine, bind preferentially to

**Figure 2** Principles of DNA hybridization and its electrochemical detection (single-surface techniques). (A) Scheme of the formation of duplex DNA (DNA hybridization) from two complementary ss oligodeoxynucleotides (ODNs). Duplex DNA is not formed when the target DNA sequence is noncomplementary. In an electrochemical hybridization detector, one of the two strands is used as a probe which is immobilized at the electrode surface. (B) Scheme of immobilization of the probe at the electrode surface. (i) at positively charged carbon electrodes DNA is adsorbed electrostatically via the negatively charged sugar-phosphate backbone. At the hydrophobic mercury electrodes, hydrophobic bases are strongly bound to the surface. (ii) Covalent binding of thiolated ODN at gold electrodes via the sulfur atom securing oriented ODN immobilization. (C) Detection of the DNA hybridization: (i) based on the formation of the hybrid duplex DNA using either (a) a redox indicator that binds preferentially to the hybrid duplex DNA and produces an oxidation (or reduction) signal: (simple intercalators and groove binders do not provide best resolution; threading intercalators or bis-intercalators with high DNA binding constant appear to be a better choice) or (b) direct measurements of changes in DNA properties (such as conductivity) due to the duplex formation. Alternatively, a reporter (signaling) probe can be used as shown in **Figure 3B**; (ii and iii) based on the determination of the target DNA at the electrode surface; (ii) a suitable enzyme such as horseradish peroxidase (HRP) is coupled to the target DNA. Upon hybridization, an electrocatalytic current due to hydrogen peroxide reduction is measured. (iii) After DNA hybridization the DNA probe serves as a primer, which is extended at the electrode surface by DNA polymerase incorporating biotinylated nucleotides in the newly synthesized strand. HRP is then attached to the DNA using streptavidin-biotin chemistry followed by measurements as in (ii); (iv) DNA probe not containing guanine is used and presence of guanine in target DNA is detected after the hybridization using guanine oxidation signals either on indium tin-oxide or carbon electrodes. (Reprinted with permission from Paleček E and Fojta M (2001) Detecting DNA hybridization and damage. *Analytical Chemistry* 73: 75A–83A; © American Chemical Society.)

thymine residues in ssDNA, while others (e.g., Os, 1,10-phenanthroline) bind both ds- and ssDNA. They produce a high electron yield catalytic signal at about  $-1.2$  V at liquid mercury and solid amalgam electrodes and quasireversible signals between  $-0.2$  and  $-0.7$  V at both carbon and mercury electrodes. Other electroactive markers such as viologen derivatives, daunomycin, and ferrocene were later coupled to nucleic acids primarily for their potential use in biosensing.

PNA is currently investigated as a possible candidate for diagnostic and therapeutic applications in medicine in the twenty-first century. In PNA, the entire sugar-phosphate backbone of DNA or RNA is replaced by *N*-(2-aminoethyl)glycine units. This structural change produced a DNA mimetic with higher binding affinity to complementary strands as compared to unmodified DNA. In contrast to DNA and RNA with negatively charged backbone, the backbone of PNA is electrically neutral. It produces

electrochemical responses of PNA at carbon and mercury electrodes similar to DNA, i.e., A and G residues in PNA are oxidized at carbon electrodes, while at mercury electrodes reduction of A, C, and G takes place. Differences in electric charges of PNA and DNA backbones are manifested by the different adsorption behavior of these two compounds as detected by a.c. impedance at mercury electrodes. PNA has been used in the development of the DNA hybridization sensors.

## DNA-Modified Electrodes

Up to the middle of the 1980s electrochemical analysis of nucleic acids was usually performed with the electrode immersed into the nucleic acid solution. To decrease the volume of the analyzed sample a simple preparation of a DNA-modified electrode was proposed in 1986. Instead of performing the voltammetric measurements with the electrode immersed into the DNA sample, the DNA-modified electrode was first prepared by immersing the electrode into a small drop of a DNA solution (10–3  $\mu$ l). Both ss- and dsDNAs were irreversibly adsorbed either at mercury or at carbon electrodes, resisting subsequent washing. At present, nucleic acid-modified electrodes prevail in electrochemical analysis of nucleic acids; covalent (e.g., via –SH groups at the end DNA molecules to gold or mercury electrodes) and noncovalent binding (e.g., strong hydrophobic interactions of the nucleic acid bases with the mercury electrodes or electrostatic binding to positively charged carbon electrodes) is used for immobilization of nucleic acids.

## DNA and RNA Sensors

In recent years, attention of scientists in nucleic acid electrochemistry has greatly increased, not only because of high sensitivity of electrochemical methods for small changes in the DNA structure, but primarily because of expectations that electrochemical DNA sensors may become important and inexpensive tools for use in many areas of human life, including decentralized detection of DNA damage and rapid diagnostics of various diseases in the physician's office. Recent progress in the development of sensors for DNA hybridization and damage is encouraging.

### DNA Hybridization

Sequencing of individual eukaryotic genomes is still too laborious and expensive. New technologies are therefore sought and among them sequencing by DNA hybridization appears most promising. At

present, DNA sequencing can be performed by means of the DNA hybridization sensors with optical detection. Recently, it has been shown that this detection can be complemented by voltammetric and chronopotentiometric methods, which are simpler and should be less expensive. DNA hybridization sensors are well suited for decentralized diagnostics and other purposes, including determination of bacteria and viruses in biological warfare.

### Single-Surface Techniques

Up to 2001, DNA hybridization sensors used single-stranded, short (15–25 nucleotides) oligodeoxynucleotide (ODN, probe DNA) immobilized on an electrode (see **Figures 2** and **3**), using PNA as a probe, appeared advantageous in the detection of point mutations. The ODN-modified electrode was immersed in target DNA solution to test its nucleotide sequence. When the sequence of target DNA matched that of the probe (based on the complementary Watson–Crick pairing), a probe–target (hybrid) duplex DNA was formed at the electrode surface. The hybridization event (DNA duplex formation) was detected electrochemically in various ways (**Figure 2**).

This system worked quite well with synthetic ODNs when probe and target DNAs were of about the same lengths. In a real DNA sequence analysis with longer polymerase chain reaction (PCR) products, viral or chromosomal DNAs, the target DNAs can be substantially longer than the probe. With longer target DNAs difficulties connected with the nonspecific DNA adsorption frequently arose, resulting in a loss of specificity and decreased sensitivity. Nevertheless, several promising single-surface techniques shown in **Figure 3** have been developed and recently reviewed by Popovich and Thorp. The eSensor™ DNA Biochip whose principles are shown in **Figure 3B** is already on the market. It is produced by Motorola. The critical components (capture probe, target probe, and signaling probe) are in the cartridge and the current produced by this system is measured and interpreted by the eSensor™ DNA Detection Reader and Software. Various eSensor™ assays are being developed, such as cytochrome P450 and cystic fibrosis assays. More details can be obtained from eSensor@motorola.com. Due to the fast progress in nucleic acid electrochemistry and sensor development, new variants of electrochemical DNA sensors may appear in the market very soon.

### Double-Surface Techniques

Optimum properties of the hybridization surface greatly differ from those of the (electrode) surface

**Figure 3** Recent single-surface DNA hybridization sensors. (A) Approach of Barton *et al.*, as described in Boon EM *et al.*, (2000) *Nature Biotechnology* 18: 1096. Alkanethiol-modified probes are attached to gold electrodes and hybridized to target DNA. In the presence of redox-active intercalator, reduction of ferricyanide in solution is observed. (B) Approach of Kayem *et al.*, as described in Umek RM *et al.* (2001) *Journal of Molecular Diagnosis* 3: 74. Alkanethiol-modified capture probes are attached to gold surfaces in the presence of phenylacetylene thiols. Hybridization of target DNA and signaling probes position ferrocene labels (Fc) adjacent to the phenylacetylene thiols, which communicate with the gold electrode. Diluent thiols are terminated with polyethylene glycol (not shown). (C) Approach of Thorp *et al.* (1998). Silane-modified capture probes are attached to ITO electrodes. Hybridization of target allows for electrocatalytic oxidation of guanine by  $\text{Ru}(\text{bpy})_3^{3+/2+}$ . Adapted from Popovich ND and Thorp HH (2002), with permission.

**Figure 4** Principles of double-surface (DS) DNA hybridization sensors. In difference to the single-surface techniques (Figures 2 and 3) in the DS sensors the DNA hybridization takes place at one surface and electrochemical detection of the hybridization event at another surface. Hybridization is performed at a relatively large surface H best suited for this purpose (e.g., magnetic beads with covalently (or avidin–biotin) bound DNA probe). Then the target DNA is released from the surface H and determined at a small detection electrode (DE, micro-, or nanoelectrodes can be used for this purpose). Alternatively, the magnetic beads with the bound target DNA can be attracted to the electrode (under which a magnet is placed) and DNA can be determined without dissociating it from the beads. In contrast to the single-surface techniques, in which the reporter (signaling) probe (RP) (see Figure 3) has to bind close to the capture probe (to communicate with the electrode). In the DS techniques the RPs can bind to any site at the target DNA. Label-free determination of long target DNA at subfemtomole level was proposed (Jelen F *et al.* (2002) *Analytical Chemistry* 74: 4788–4793). Various electroactive DNA labels were designed, such as metal nanoparticles, osmium complexes, enzymes, and enzyme-linked immunoassays. Carbon, solid dental amalgam, and mercury electrodes were mainly applied.

used for the electrochemical detection, thus making optimization of both hybridization and detection at a single surface difficult. Recently, a new method has been proposed in which DNA hybridization is performed at one surface (surface H) and electrochemical detection at the detection electrode (DE) (Figure 4).

Commercially available magnetic beads with attached probe ODN served as surface H; due to minimum nonspecific DNA adsorption at the beads, very high specificity of the DNA hybridization was achieved. Optimum DE was chosen only with respect to the given electrode process. Detection of relatively long target DNAs was possible (1) by enzyme-linked immunoassay of target DNA modified by osmium tetroxide, 2,2'-bipyridine (Os,bipy) at carbon DEs (direct determination of Os,bipy at mercury and carbon electrodes was also performed) and (2) by using CSV at mercury or solid mercury

amalgam DEs for the determination of purine bases, released from DNA by acid treatment. CSV in the presence of copper allowed determination of sub-nanomolar concentrations of DNA. Long target DNAs in the presence of a large excess of nonspecific DNA were easily analyzed by techniques mentioned under points (1) and (2). These techniques are well suited also for analysis of RNAs, which have been analyzed to a lesser extent.

Many advantages of the double-surface technologies over the single-surface ones were discussed in the literature. In addition to higher specificity and easy work with long target DNAs, it is the larger choice of electrodes (such as mercury and solid amalgam ones) and methods for the DNA determination that are not limited by requirements for easy immobilization of the DNA probe at the electrode surface. This greatly increases possibilities in DNA detection, including use of reporter probes (which can bind to target DNA regardless of the distance from the capture probe at the surface), application of well-established techniques, such as avidin–biotin, immunoassays, nanoparticles, to detect the target sequence. Recent application of the double-surface technology has already resulted in an increase in sensitivity of DNA detection by several orders of magnitude, simultaneous detection of multiple DNA targets, determination of lengths of DNA repetitive sequences such as those characteristic for some neurodegenerative genetic diseases. Magnetic beads can be incorporated into microfluidic systems and are well suited for the development of the lab-on-chip suitable for analysis of DNA hybridization and DNA damage starting with a drop of blood. Such a module-composed device is being developed by November AG in collaboration with Siemens Medical Solutions. The central element of this device is an exchangeable credit card-sized cartridge with a microchannel structure that integrates all the steps including nucleic acid isolation, PCR, and electrochemical detection of the hybridization event. More details can be found at <http://www.november.de>.

With both single- and double-surface techniques detection of single-base mismatches (point mutations) is possible. At present principles of the electrochemical detection of the DNA hybridization event and determination of various genomic nucleotide sequences, after the PCR amplification of DNA, are known. On the other hand, a lot of work has to be done to develop and optimize inexpensive and simple electrochemical DNA sensors with performance comparable to that of DNA arrays based on optical detection. Determination of nucleotide sequences without DNA amplification represents a great challenge. To reach this goal it will be necessary to

increase further the sensitivity of the electrochemical detection and to solve the problem of an extremely high excess of nonspecific DNA that interferes with the analysis of unamplified genomic sequences.

In recent years, substantial progress in studies of the DNA conductivity was achieved but many questions still remain to be answered. One of the most exciting discoveries is the change in the electrical properties of dsDNA upon introduction of a base mismatch, demonstrated by a number of authors using different approaches. Elucidation of the DNA conductivity may help not only to understand better many biological processes, including mutagenesis, carcinogenesis, and DNA repair, but it can be also utilized for the development of DNA sensors.

### DNA Damage

DNA in living organisms is a critical target of various agents, including oxidative metabolism, photoexcited dyes, radiation, and other agents that induce damage of bases and/or ruptures of the sugar–phosphate backbone. Products of DNA damage may be involved in mutagenesis, carcinogenesis, and cell lethality. Development of sensitive and fast assays of DNA damage has recently attracted increasing attention among analytical chemists. The sensitivity of these assays must be high enough to allow detection of one damaged nucleotide in  $10^4$ – $10^7$  intact nucleotide residues in microgram amounts of DNA.

A number of methods were developed involving separation of DNA; damaged entities are separated by liquid chromatography, gas chromatography, or capillary electrophoresis and detected online by various techniques such as mass spectrometry, amperometry, fluorimetry, and radioactivity measurement. Alternatively, DNA lesions can be measured without hydrolyzing DNA by immunoassays, sedimentation, or gel electrophoresis that quantify the number of strand breaks in unhydrolyzed DNA samples. These techniques are useful, but not one of them can serve as a fast response sensor providing information about the DNA damage in seconds or minutes.

Recently, electrochemical methods for the determination of DNA strand breaks at an electrode have been developed. With these methods, one single-strand break (ssb) among  $>2 \times 10^5$  intact phosphodiesteric bonds can be determined in submicrogram amounts of DNA. Circular covalently closed supercoiled (sc) DNA is attached to HMDE. If there is a strand break a new electrochemical signal appears (Figure 5A).

This signal is due to bases at the strand interruption interacting with the electrode and can be obtained by

**Figure 5** Detection of DNA damage with supercoiled (sc) DNA-modified electrodes. (A) AC voltammetric peak 3 is due to desorption of DNA segments adsorbed at mercury electrodes via bases. In scDNA bases are not available for the interaction with the electrode surface and peak 3 is not observed. Introduction of a strand break (sb) in scDNA results in a better accessibility of bases in the vicinity of the sb and in formation of peak 3. Peak 3 can be thus used for the detection of DNA cleavage by different agents, including radiations and free radicals. In difference to the mercury electrodes, carbon electrodes are little sensitive to sb in DNAs. (B1) scDNA is treated with a DNA-cleaving agent in solution followed by DNA adsorption at the electrode. After washing, the electrode is transferred into a cell and DNA voltammetric response is measured. (B2) Intact scDNA adsorbed at the electrode serves as a sensitive layer of a biodetector for DNA damage. (C) Damage to DNA bases can be transformed to DNA strand breaks and/or single-stranded DNA regions by DNA repair enzymes. For example, exonuclease III (Exo III) cleaves the DNA sugar-phosphate backbone at abasic sites resulting from spontaneous release of dimethylsulfate (DMS)-methylated guanine. This strand cleavage is followed by exonucleolytic degradation of one DNA strand creating segments of ssDNA which are sensitively detected through peak 3. DNA lacking damaged bases are not cleaved showing an electrochemical response similar to that of undamaged DNA. (Reprinted with permission from Paleček E and Fojta M (2001) Detecting DNA hybridization and damage. *Analytical Chemistry* 73: 75A–83A; © American Chemical Society.)

different methods such as a.c. voltammetry and constant current chronopotentiometry. Either the DNA which was damaged in solution can be immobilized at the electrode surface (to determine the strand breaks) or the electrode modified with intact scDNA

can be used as a recognition layer to detect DNA-damaging agents present in the medium into which the electrode is immersed. Primary strand breaks and/or damage to bases, transformed by the activity of enzymes or chemicals into breaks or single-stranded regions (Figure 5), can be determined. To overcome the difficulties associated with liquid mercury electrode in the field, the HMDE can be replaced by a mercury film carbon or solid dental amalgam electrodes. This electrochemical DNA detector responds in seconds, being much faster than the currently used electrophoretic methods.

## DNA-Protein Interactions

Interactions of DNA with proteins and peptides are of crucial importance in many life processes. These interactions are intensively studied by various methods but electrochemical analysis has been little utilized for this purpose. This is surprising because not only DNA is electroactive but also proteins produce various kinds of electrochemical signals. Recently, a great increase in sensitivity in protein and peptide analysis has been reached by means of constant current chronopotentiometric stripping analysis (CPSA). This method appears very attractive for protein analysis offering sensitivity by one to three orders of magnitude higher than that of previously used polarographic or voltammetric methods. CPSA signals of proteins and peptides at carbon electrodes are based on the oxidation of tyrosine and tryptophan residues and take advantage of the sophisticated baseline correction available in CPSA. At the mercury electrodes peptides and proteins yield catalytic peak H at highly negative potentials (close to  $-1.7$  V against SCE) allowing determination of some peptides and proteins at femto- and subfemtomole levels. Such a high sensitivity may find use in proteomics, e.g., in the detection of proteins expressed at low level. As a result of the recent progress in the analysis of proteins and nucleic acids the electrochemical techniques appear ready for studies of sequence-specific and nonspecific DNA-protein interactions. The number of proteins known to interact with DNA is large, including transcription factors, antibodies, oncoproteins. Electrochemical studies may involve not only DNA-protein interactions in solution but also interactions with one component immobilized at the electrode surface and the other in solution; introducing an electric charge to the electrode (resembling the situation at living cell interfaces) during the DNA-protein interactions might provide a new biophysical dimension to these studies. Recently, some reports about electrochemical analysis of the tumor suppressor protein p53 and its DNA binding

have appeared. Also, changes in the DNA conductivity resulting from specific interactions of some proteins with DNA have been reported.

## Introduction

Nucleic acid analysis involves the determination of particular sequences of bases. Because of the low concentrations of individual sequences in most samples, enzymatic amplification processes such as polymerase chain reaction (PCR) must be integrated into the assay to enrich the sample for the sequences of interest. These amplification processes are never completely specific, and unless the assay is to rely solely on sequence selection during PCR, postamplification analysis is required to confirm the identity of

the amplified sequences. Hybridization to an oligonucleotide probe is the most common means to confirm specificity of deoxyribonucleic acid (DNA).

Enzyme-linked immunosorbent assays (ELISAs) are sensitive enough to detect relevant concentrations of small molecules and proteins. Their detection limits are inadequate for direct analysis of DNA in most cases. For this reason, it was not until the development of PCR that nucleic acid analysis became routine. Prior to PCR, the large quantities of nucleic acid required for hybridization precluded routine use and mandated the use of radioactive probes. After PCR, the abundance of amplified sequences allowed many methods of detection. In this environment, it was natural that immunochemical technologies first developed for immunoassay would be applied to analysis of amplified DNA.

## Introduction

Nucleic acid analysis involves the determination of particular sequences of bases. Because of the low concentrations of individual sequences in most samples, enzymatic amplification processes such as polymerase chain reaction (PCR) must be integrated into the assay to enrich the sample for the sequences of interest. These amplification processes are never completely specific, and unless the assay is to rely solely on sequence selection during PCR, postamplification analysis is required to confirm the identity of

the amplified sequences. Hybridization to an oligonucleotide probe is the most common means to confirm specificity of deoxyribonucleic acid (DNA).

Enzyme-linked immunosorbent assays (ELISAs) are sensitive enough to detect relevant concentrations of small molecules and proteins. Their detection limits are inadequate for direct analysis of DNA in most cases. For this reason, it was not until the development of PCR that nucleic acid analysis became routine. Prior to PCR, the large quantities of nucleic acid required for hybridization precluded routine use and mandated the use of radioactive probes. After PCR, the abundance of amplified sequences allowed many methods of detection. In this environment, it was natural that immunochemical technologies first developed for immunoassay would be applied to analysis of amplified DNA.

Only limited development of new methodologies has taken place for immunochemical analysis of nucleic acids. Most published methods rely on modifications to classical DNA probe hybridization or immunoassay methods, with considerable blending of the two. For example, some methods employ immobilized oligonucleotide probes to capture the analyte DNA followed by immunoenzymatic detection. Other methods use immunocapture followed by detection with an enzyme-labeled DNA probe. Distinctly new methodologies mostly impact on assay formats (e.g., DNA microarrays and *in situ* hybridization) and detection reagents (e.g., chemiluminescent enzyme substrates).

## Immunoreagents for Nucleic Acid Detection

Antibodies are immunoreagents. Considering the ligand–receptor basis for immunochemistry, avidin and biotin are often considered immunochemical reagents. The literature is replete with assays that employ immunological methods to increase sensitivity or specificity of nucleic acid analysis.

### Antibodies

Monoclonal or polyclonal antibodies comprising the complete immunoglobulin structure or recombinant single-chain antibodies, even incorporating only the variable regions, can be used in two modes: as immunocapture or immunodetection reagents.

A significant limitation on the use of antibodies for DNA analysis is the relatively low affinity reflected in the dissociation constant ( $K_d$ ).  $K_d$  for an antibody is defined as the antigen concentration required to saturate one-half the binding sites on the antibody. Hence, one-half  $K_d$  can be considered the effective detection limit. Dissociation constants for antibody–antigen interactions usually fall within the range of  $10^{-7}$ – $10^{-11}$  mol l<sup>-1</sup>. Yet, the concentration of analyte DNA is typically much lower. For example, 1 µg of DNA in 100 µl contains  $\sim 10^5$  copies of a single-gene sequence or  $10^{-15}$  mol l<sup>-1</sup>. Rare targets can be even more dilute, approaching zero in the clinically asymptomatic stage. For example, 1000 virions ml<sup>-1</sup> of plasma represents an analyte concentration of  $10^{-18}$  mol l<sup>-1</sup>.

### Avidin and Biotin

Avidin is a tetrameric glycoprotein isolated from egg white. Bacterial streptavidin lacks carbohydrate side chains. Both proteins bind four biotin molecules per tetramer with dissociation constants approaching  $10^{-15}$  mol l<sup>-1</sup> for avidin and  $\sim 10^{-14}$  mol l<sup>-1</sup> for

streptavidin. Affinity is greater than that of most monoclonal antibodies for their haptens. Streptavidin has gained a reputation for lower backgrounds due to the lack of carbohydrate side chains that promote nonspecific interactions, although design of an efficient blocking reagent is an advantageous way to approach the problem, while maintaining the tighter binding and lower cost of avidin.

### Nucleic Acid Probes

Cooperativity in base-pairing between two strands of DNA results in tight binding for perfectly matched oligonucleotides that depends on sequence and length of the probe and on ionic strength, ionic composition, and temperature. The feasibility of using oligonucleotides for hybridization to targets approaching infinite dilution is amply demonstrated by PCR primers.

## Assay Considerations

### Qualitative Assays

Immunochemical methods perform well to rapidly screen hundreds or thousands of samples for the presence of the target gene sequence. Immunoreagents in combination with high-performance PCR can enable low-cost, high-throughput detection of very few copies of analyte.

### Quantitative Assays

Immunoreagents are well suited for quantitation of amplified DNA. However, the exponential nature of PCR amplification makes it difficult to extrapolate from the amount of amplified DNA to the amount of starting material. The most reliable quantitative PCR methods involve real-time assay of amplified DNA during the exponential phase of the amplification reaction. Because the analyte of interest is usually the DNA template, not the amplification product, immunochemical methods at their present stage of development are generally best applied to an unamplified template where concentrations permit direct analysis or for qualitative assays.

### Sequence Discrimination

Molecular genetics assays can be designed to amplify both normal and mutant alleles, then to determine which allele is present in a postamplification phase of the analysis. For detection of single base changes, a generic amplification is conducted with primers that flank the site of the mutation. Following PCR, oligonucleotide probes for wild type or mutant are

hybridized under the requisite stringency followed by immunoenzymatic detection.

### Assay Components

Immunoassays for nucleic acids usually employ a solid phase on which the analyte is immobilized either before or after hybridization. Two general configurations, immunocapture or hybridization capture (enzyme-linked oligonucleotide-sorbent assay or ELOSA), are possible (Figure 1). Careful design and optimization of each component can yield a high-performance assay. Typical components for a micro-well PCR immunoassay are provided in Table 1.

### The Solid Phase

The ideal solid phase would permit specific, directional attachment of binding moieties, then complete blocking of the remaining surface to analyte, detection reagents, and visualization reagents. Such a solid

support would be highly hydrated and nonreactive. No such ideal solid phase has yet been described.

In general, any material that binds nucleic acids can be used as the solid phase. The ideal solid phase is one with high selectivity for nucleic acids over proteins. The solid phase must not react with the enzyme substrate itself. A final criterion is that the solid phase must bind sufficiently tightly so that nucleic acids will not be lost during blocking, washing, or detection steps. Solid phases that allow covalent immobilization of DNA are preferable but are not required.

Original ELISA plates were polystyrene and were not suitable for hybridization at temperatures much above 50°C due to deformation of the plastic. Plates of polycarbonate, polyvinyl, and other materials and with proprietary surface treatments to reduce non-specific binding are now available. Novel surfaces, including nonplastic solid supports, are incorporated into commercial products. Polypropylene exhibits very low binding of DNA and is not suitable as a solid phase without surface modification.

Classic methods for nucleic acid detection relied on electrophoresis followed by blotting to filter membranes. Membranes that have been used for this purpose include nitrocellulose, nylon (either unmodified, positively charge modified, or negatively charge modified), and poly(vinylidene fluoride). Nucleic acids bind very tightly to such membranes regardless of the net charge on the membrane. The use of negatively charged nylons may be advantageous for background reduction due to charge repulsion of protein reagents. DNA microarray chips use silica-based solid phases to which DNA is bound either covalently or by adsorption.

Polystyrene particles, sometimes called 'latex' microparticles (not to be confused with latex rubber material), and paramagnetic microparticles are widely used.

**Figure 1** Immune complexes formed in typical PCR immunoassay. The two general configurations for DNA immunoassay that are shown differ in the means of capture. Analyte DNA is assumed to have been amplified with a 5'-biotinylated primer. In the immunocapture approach, biotin provides the means for capture onto an avidin-coated multiwell plate. In the hybridization approach, the analyte is captured by hybridization to an immobilized probe followed by immunoenzymatic detection with an avidin-alkaline phosphatase conjugate.

### The Capture Reagent

With the exception of materials to which nucleic acids bind directly (e.g., nylon, silica), an intermediary is required to bind the DNA or ribonucleic acid (RNA) to the solid phase. Two general approaches have been used: immunocapture and hybridization capture (ELOSA) (Figure 1).

**Table 1** Components of a typical PCR immunocapture assay

Reagent	A typical composition
Plate coating solution	50 µg ml <sup>-1</sup> avidin, 50 mmol l <sup>-1</sup> sodium hydrogencarbonate, 150 mmol l <sup>-1</sup> NaCl, pH 8.5
Wash solution	Phosphate-buffered saline (0.02 mol l <sup>-1</sup> sodium phosphate, 0.85% NaCl, pH 7.4), 1% Tween 20
Blocking solution	Wash solution + 5% fish skin gelatin
Hybridization solution	Alkaline phosphatase labeled probe diluted to 10 nmol l <sup>-1</sup> in blocking solution

**Immunocapture** Immunocapture uses a solid phase coated with avidin or streptavidin to capture nucleic acids containing biotin. Biotin is introduced into the nucleic acids by the use of a biotinylated deoxyribonucleoside triphosphate (dNTP) or a 5'-biotinylated primer during PCR amplification. Haptens such as digoxigenin or fluorescein are also widely used in combination with monoclonal antibodies.

Immunocapture requires adequate loading of the solid phase to bind not only the biotinylated analyte DNA but also the biotinylated dNTP or primer that is present in large excess. dNTPs in a typical amplification reaction are each present at  $200\ \mu\text{mol l}^{-1}$ . Modified dNTP is added at  $1\text{--}10\ \mu\text{mol l}^{-1}$  to avoid inhibiting amplification. Variable incorporation of modified dNTPs by DNA polymerase is affected by DNA sequence such that the use of modified dNTPs is problematic as a general approach. Biotinylated primers are typically used at  $0.1\text{--}0.5\ \mu\text{mol l}^{-1}$ . High-purity primers are routinely synthesized using biotin phosphoramidites on automated DNA synthesizers and can be purified by HPLC if necessary. A label on the 5'-end of a PCR primer has no practical effect on amplification, unlike the presence of a modified dNTP. For these reasons, modified primers are the preferred approach.

Adsorption of an immunocapture reagent to polystyrene wells in a microtiter plate is as simple as antibody coating of an ELISA plate. Coating for a DNA probe assay should use a plate that is qualified for high protein binding capacity and low well-to-well variation. Coating solution should contain at least  $100\ \mu\text{g ml}^{-1}$  avidin for maximum loading. Because passive adsorption depends on hydrophobic interactions, somewhat higher loadings may be obtained with pH at the isoelectric point, and coating solutions typically contain  $0.1\text{--}0.2\ \text{mol l}^{-1}$  salt. Coated plates should be washed with the same 'wash solution' that will be used in the assay to remove incompletely adsorbed proteins.

**Hybridization capture** The alternative to immunocapture is hybridization capture (ELOSA). Oligonucleotide probes are coupled to the solid phase with

a suitable spacer to minimize steric hindrance and electrostatic repulsion from the surface. Analyte nucleic acid is captured by hybridization to the immobilized probe. Many approaches have been described for chemically binding oligonucleotides to polystyrene surfaces, and a few have used passive adsorption. Surface-modified plates suitable for binding amine-modified oligonucleotides are commercially available.

Assays that employ an oligonucleotide capture probe are termed ELOSA by analogy to ELISA.

### Reporter Groups

Because of the need for sensitivity, most labels for DNA analysis are enzymes or highly efficient fluorophores such as phycobiliproteins. The most commonly used enzyme labels are calf intestinal alkaline phosphatase and horseradish peroxidase (Table 2). Beta-galactosidase is used primarily for gene expression monitoring. Other enzymes such as glucose-6-phosphate dehydrogenase have not found as wide utility as phosphatase and peroxidase.

A reporter enzyme may be directly coupled to the DNA probe such that no secondary binding step is required. Alternately, the enzyme is conjugated to avidin or a monoclonal antibody that binds to a hapten label on the DNA probe. Assays that use direct enzyme-labeled probes are capable of extremely low backgrounds and can be operationally simpler and hence less expensive, faster, and more amenable to high-throughput screening.

**Enzyme substrates** Considerable development has taken place in the field of new enzyme substrates, most notably the addition of several stable chemiluminescent substrates for alkaline phosphatase and peroxidase (Table 3).

Colorimetric reagents generate a color change upon reaction with the reporter enzyme. Color changes are advantageous for rapid tests because they can be detected visually. Precise quantitation or assay automation requires absorbance (optical density, OD) measurement, and a wide variety of spectrophotometric and filter colorimeters are commercially

**Table 2** Enzymatic parameters for alkaline phosphatase and horseradish peroxidase

	<i>Alkaline phosphatase (calf intestinal)</i>	<i>Horseradish peroxidase</i>
Molecular weight	140 000	40 000
Reaction	Cleavage of phosphate, release of monophosphate	Oxidation by $\text{H}_2\text{O}_2$ of substrate
Optimum pH	9.8	7.0
Reaction temperature	$37^\circ\text{C}$	$25^\circ\text{C}$
Cofactor requirements	$\text{Zn}^{2+}$ , $\text{Mg}^{2+}$	None
Isoelectric point	5.7	7.2
Inhibitors	EDTA, other chelators, pH <6	Cyanide, sulfide, azide

**Table 3** Substrates for alkaline phosphatase and horseradish peroxidase

Enzyme	Substrate	Product	Readout
Alkaline phosphatase	<i>p</i> -nitrophenyl phosphate (PNPP)	Soluble, yellow	
	Nitroblue tetrazolium (NBT) in combination with 5-bromo-4-chloro-3-indolylphosphate (BCIP)	Insoluble, purple	
	4-Methylumbelliferyl phosphate (4-MUP)	Fluorescent	358 nm excitation, 450 nm emission
	Fluorescein diphosphate	Fluorescent	490 nm excitation, 520 nm emission
	2'-[2-Benzothiazoyl]-6'-hydroxybenzothiazole phosphate [BbTP] (AttoPhos)	Fluorescent	435 nm excitation, 555 nm emission
	1,2-Dioxetanes (LumiPhos, CSPD)	chemiluminescent	
Horseradish peroxidase	3-Amino-9-ethylcarbazole (AEC)	Insoluble, red	
	3,3'-Diaminobenzidine (DAB)	Insoluble, brown	
	4-Chloro-1-naphthol	Insoluble, blue-black	
	3,3',5,5'-Tetramethylbenzidine (TMB)	Soluble, yellow	OD at 450 nm
	2,2'-Azinobis(3-ethylbenzthiazoline-6-sulfonic acid) (ABTS)	Soluble, green	OD at 410 nm and 650 nm
	<i>o</i> -phenylenediamine (OPD)	Soluble, brown	OD at 492 nm
	10-Acetyl-3-dihydroxyphenoxazine (Amplex Red)	Resorufin	OD at 563 nm; or 530 nm excitation, 590 nm emission
	Luminol, enhanced luminol	Chemiluminescent	
	Lumigen PS substrates	Chemiluminescent	

available for this purpose. Despite the development of improved light emitting substrates, continued interest in colorimetric reagents is due to two factors. First, their cost is generally lower than the cost of more sensitive substrates. In particular, the cost of instrumentation to read OD is low relative to fluorescence and chemiluminescence detectors. Second, adequate sensitivity is achievable by adjusting either incubation time of the enzymatic visualization reaction or the DNA amplification step prior to hybridization analysis. Because of its higher turnover number, peroxidase is the preferred label for colorimetric detection. Phosphatase assays will require longer incubation times, up to 1 h, whereas peroxidase assays are complete within 10 min. Although signal can be accumulated over time to enhance weak signals, background also increases.

Fluorescent substrates are nonfluorescent until a quenching group is cleaved by the reporter enzyme, or enzyme action results in a shift in fluorescence emission. Generally, fluorescence detection can be more sensitive than OD methods. Whether a theoretical increase in sensitivity is realized depends on the choice of enzyme and substrate as well as many other assay parameters.

Chemiluminescent substrates offer maximum sensitivity for reporter enzyme detection with a dynamic range of five orders of magnitude. Historically, their use has been limited by poor stability to heat and light. Developments over the past ~20 years,

however, have yielded stable chemiluminescent substrates for alkaline phosphatase and beta-galactosidase. With these materials, less than  $10^{-19}$  mol of alkaline phosphatase can be measured. Parallel development of peroxidase substrates has resulted in stable luminophores with sustained light yields to take advantage of the more rapid kinetics of the peroxidase reaction. The most developed of these reagents enables detection of peroxidase with similar detection limits and the same instrumentation as for the alkaline phosphatase substrates. With glow-type reagents that produce sustained light output over many minutes, signal accumulation is possible by instrumental integration. Chemiluminescence readers are widely available in single-tube and multi-well formats. Instrumentation can be programmed to read in either steady-state or kinetic mode.

Further enhancement in detection sensitivity of reporter enzymes is achievable by enzyme amplification or cascade reactions often termed 'enzyme cycling' assays. One approach is to use alkaline phosphatase as the reporter enzyme. Phosphatase cleavage of NADP forms NAD, which enters cyclic reactions catalyzed by alcohol dehydrogenase and diaphorase. Each turnover of phosphatase substrate initiates a cascade resulting in numerous detectable product molecules. Such approaches, perhaps incorporating chemiluminophores as the terminal product, hold promise for further extension of the sensitivity of immunoenzymatic methods.

## Blocking Solutions

Complete coating of the solid phase will eclipse sites on the solid phase where antibody conjugates or reporter enzymes might bind. In addition, a 'blocking solution' containing proteins and nonionic detergents is typically incubated with the solid phase prior to addition of analyte.

Early blocking reagents tended to be those that were familiar from Southern blotting: salts, polymers (dextran sulfate, polyvinylpyrrolidone), and non-homologous DNA. Later, protein-based blocking reagents such as bovine serum albumin or gelatin came into use. Low-lipid casein (Hammarsten grade) proved advantageous for use with alkaline phosphatase. Gelatin from coldwater fish provides substantial improvement over previous reagents.

Detergents are components of many blocking reagents. Classical Southern blot methodology using sodium dodecyl sulfate (SDS) is typically modified by substitution of more enzyme-compatible nonionic detergents such as polyoxyethylene (20) sorbitan monolaurate (Tween 20) or octylphenolpoly(ethyleneglycolether) (Triton X-100). SDS at low concentrations may preclude enzyme activity but may not irreversibly inactivate enzymes. Therefore, it and other strong detergents may be used during hybridization and subsequent detection steps, provided concentrations are reduced by washing to allow activity by the detection reagents. Because SDS denatures proteins, the concentrations at which it can be used depend on temperature. Generally speaking,

higher concentrations can be tolerated if the assay temperature is 42°C than if it is 60°C. Given that both alkaline phosphatase and horseradish peroxidase for immunoassay are purified from natural sources, the actual concentration of SDS that can be used may also depend on stability of the particular enzyme preparation.

Several important considerations in the design of a blocking reagent are listed in **Table 4**. It is not possible to list acceptable ranges for each of these parameters because they depend on the reagents, the solid phase, and assay specifications.

Most of the background signal in immunoassay of amplified DNA comes from nonspecific binding of enzymatic detection reagents to the solid phase. Therefore, attention should be paid to 'blocking reagent' design to block nonspecific binding by protein components. The nonionic detergent Tween 20 has been reported to block both nonspecific binding sites on the solid phase and nonspecific interactions between assay reagents.

## Wash Solutions

After immunocapture and immunodetection, the solid phase must be washed to remove weakly or nonspecifically adsorbed reagents. A pH and salt concentration should be chosen to maintain specific interactions between assay reagents and analyte. Detergents, preferably enzyme-compatible nonionic detergents, are included to facilitate desorption of loosely bound reagents. Similar considerations

**Table 4** Parameters for blocking, hybridization, and immunobinding reagent design

pH		Avoid inactivation of reporter enzyme Near isoelectric point, proteins may tend to bind to hydrophobic surfaces The pH must support hybridization and/or immunochemical reactions to be performed in the blocking solution
Detergents	0.1–2.0%, Triton X-100, Tween 20	Avoid inactivation of enzyme reagents Nonionic detergents are preferable Low concentrations of anionic detergents may be used with adequate washing
Protein blockers	Bovine serum albumin, gelatin, fish skin gelatin	For maximum sensitivity, must be free of proteases and nucleases Fish skin gelatin is preferred
Nucleic acid blockers	Herring sperm DNA, salmon sperm DNA	Not required
Polymers	Ficoll, dextran sulfate, polyvinylpyrrolidone, poly(ethylene glycol)	Not required
Salts	0.1–0.2 mol l <sup>-1</sup> NaCl, saline sodium citrate (SSC), saline sodium phosphate–EDTA (SSPE)	Salt concentration must support immunocapture or immunodetection reactions
Chelators	Ethylenediaminetetraacetic acid (EDTA)	Compatible with peroxidase not compatible with alkaline phosphatase

pertain to the ‘wash solution’ as for the ‘blocking solution’.

While the ideal wash regimen for hybridization with oligonucleotide probes on the solid phase is undoubtedly different from that for detection with enzyme conjugates, in practice, the same ‘wash solution’ is used. Most commonly, hybridization and capture are performed simultaneously or in series with no intervening wash step. Finally, a single ‘wash solution’ is used to wash the solid phase at least thrice before addition of substrate.

Assay Configurations

Direct Assays for Unamplified DNA

Assays for low-copy targets must amplify before the immunochemical step or must configure the assay in such a way that antigen concentration is close to the  $K_d$  for antibody binding. Some amplification of antibody-binding sites can be achieved by the use of long probes incorporating multiple haptens. Hybrid capture assays are commercially available for hepatitis B virus, human cytomegalovirus, and human papillomavirus. All of these pathogens express DNA at a high level during active infection. Viral DNA is captured onto a solid phase by immobilized RNA probes. RNA–DNA hybrids are detected using alkaline phosphatase-conjugated monoclonal antibodies to RNA–DNA duplex. Through the use of long RNA probes, multiple sites are generated for enzyme conjugate binding. Despite their success in specific cases, such approaches remain problematic for low-copy targets.

Immunoassays are ideal for measuring the extent of DNA damage. Many mutagens chemically react with DNA to form adducts. Oxidative damage to DNA produces several modified bases including 8-oxoguanine. Adducts, modified bases, and abasic sites resulting from excision repair of damaged bases can be assayed using typical immunoassay formats with antibodies against the modified base and a fluorescent or chemiluminescent label. Immunohistochemical approaches have been more common, but competitive and noncompetitive ELISA assays for modified bases have been described. Recently described methods have employed avidin to detect sites of DNA damage that have been tagged with biotin.

Hybridization Analysis of Amplified DNA

While immunoenzymatic detection can increase sensitivity of amplified DNA detection (e.g., by detection of label incorporated during amplification), virtually all applications of immunoreagents in PCR have utilized probe hybridization for increased

specificity. Double-stranded PCR products must be denatured by heat, organic solvents, or other methods, prior to hybridization.

Hybridization Combined with Separation

Genomic DNA is separated according to size by electrophoresis, then transferred to a filter membrane where it is immobilized. The resulting Southern blot (or Northern blot, in the case of RNA) can be hybridized to a probe, then stained to visualize the particular DNA fragments that hybridize to the probe. The combination of hybridization with a size criterion for identification increases specificity but reduces sensitivity.

Hybridization without Separation

**Dot blots** The popularity of size-fractionated DNA immobilized on filters led to the application of similar detection methods for DNA simply spotted on filters without prior electrophoresis. These methods are generally referred to as dot blots or spot blots. In general, identical detection methods may be employed as for Southern or Northern blots. Without size separation, particular attention must be paid to hybridization stringency so that high backgrounds do not confound data interpretation. Dot blots are best suited to high-throughput screening assays. Reverse dot blots involve immobilization of probe rather than analyte.

**Microtiter plate** Configuration for parallel assay is an important consideration if high-throughput analysis is contemplated. While filter plates and manifolds that can be disassembled and cleaned after each dot blot experiment are widely used, most ‘homebrew’ DNA immunoassays have used commercially available plates for ELISA. Microtiter (96-well) plates allow assays to be conducted with multichannel pipettors and automated robotic workstations. Higher-order multiplexing with 384-well or 1024-well plates is possible. A typical assay protocol is provided in Table 5.

**DNA microarrays** DNA microarrays provide a means for parallel analysis of thousands of sequences in a single experiment. The original DNA arrays

Table 5 General procedure for PCR immunocapture assay

Denature the nucleic acid analyte
Add analyte to hybridization solution in coated, blocked microwell
Incubate for 20 min at 42°C
Discard hybridization solution
Wash with wash solution
Add substrate and detect as appropriate to the substrate

used immobilized oligonucleotides tethered to silica chips. Analyte RNA was tagged with fluorescein, hybridized to the chip, and detected by fluorescence. Subsequent developments have led to a wide variety of methods for preparing the microarrays as well as performing the labeling and hybridization. Immunochemical techniques involving reporter enzymes are not well suited for these methods due to the short distances between various probes on the chip surface. High-sensitivity detection is currently achieved by incorporation of biotin into the analyte followed by hybridization on the chip and detection with streptavidin-conjugated phycoerythrin.

***In situ* hybridization and *in situ* PCR** *In situ* hybridization provides information on spatial localization, within a cell or tissue, of a particular nucleic acid, usually a messenger RNA (mRNA) or a pathogen's DNA or RNA. Similar considerations apply to assay formats and labels as apply for the analysis of purified nucleic acids. The main difference is that the specimen must first be fixed prior to immunochemical and hybridization analysis. Insoluble substrates are used to prevent diffusion of signal from one point to another. Methods have been devised for PCR amplification in fixed cells (*in situ* PCR). Immunochemical detection by fluorescence (fluorescence *in situ* hybridization) using digoxigenin and fluorescent anti-digoxigenin antibodies has been reported, as have techniques incorporating antibodies conjugated to colloidal gold (ImmunoGold) with or without enhancement by silver deposition.

## Introducing Labels

Unless hybridization to two probes is contemplated (sandwich hybridization), nucleic acids to be analyzed must be labeled for capture or detection.

### Labeling the Analyte

When the analyte is amplified prior to analysis, labeling is greatly simplified. Several methods for incorporating detectable labels have been described. Labeled dNTPs allow more labels per analyte, but in practice the increase in sensitivity is offset by cost and background. A labeled primer allows efficient, uniform labeling during amplification. The label can be used for detection or for capture.

**Modified dNTP approach** Either capture labels or detection labels can be incorporated during amplification or primer extension. The amount of signal enhancement, however, is limited by steric hindrance. Labeled nucleotides must be stable to the conditions employed in amplification. To minimize steric

hindrance during polymerase incorporation, long spacer arms generally are recommended. Even so, no available modified dNTP is incorporated as efficiently as the unmodified dNTP. A variety of labeled dNTPs are available, including biotin, digoxigenin, and various fluorophores. In principle, antibodies could be raised against any of these labels and employed as either capture or detection moieties.

The cardinal disadvantage of the labeled dNTP approach is a nonspecific signal that arises from incorporation of the label into primer oligomer and other nontarget-derived amplification products. A second disadvantage is the excess label that must be somehow washed off the solid phase to avoid increased assay background. A third disadvantage is expense.

**Labeled primers** Oligonucleotide primers are easily labeled on the 5'-phosphate group with biotin, digoxigenin, dinitrophenol, other haptens, fluorescein, other fluorophores, and many other reagents. These labels can be used for either capture or detection. To increase specificity, the primer label is generally used for capture, rather than for detection. Thus, hybridization to a labeled oligonucleotide probe can be performed in solution where kinetics are more rapid, and followed by capture on the solid phase.

For example, a solid phase coated with avidin or streptavidin can be used to capture hybrids containing a biotinylated primer. Subsequent detection reactions involve the label that is attached to the probe (Figure 1). Solid phases also can be coated with monoclonal or polyclonal antibodies. Cost and availability are considerations that have prompted many researchers to use avidin.

Labeled primers can be used for both capture and detection. The sense-strand primer can be labeled with a capture reagent such as biotin, and the anti-sense-strand primer can be labeled with a detectable reagent such as digoxigenin. This combination is capable of high sensitivity but suffers from background due to primer oligomer and nonspecific products unless PCR is well designed and optimized.

**Labeling unamplified nucleic acids** Chemical methods to label unamplified nucleic acids include photoactivatable biotin reagents and sulfonation of cytosines. Enzymatic labeling using random primer extension is also possible. Extension of oligodeoxythymidine primers hybridized to the 3'-polyadenylate sequence in mRNA can be used to generate labeled antisense RNA for analysis.

### Labeling the Probe

**DNA probes** Long DNA probes can be generated using recombinant DNA techniques as inserts in

plasmids. Linearization of plasmid DNA yields a DNA probe of several hundred to several thousand base pairs in length. A standard method of random priming or nick translation is used to introduce labels into this probe. DNA probes can be labeled with photoactivatable biotin or by any methods used to label analyte DNA.

Shorter DNA probes (less than ~50 bases) are usually synthesized. A wide variety of labels are available as phosphoramidites for automated incorporation at 5', 3', or internal positions in the oligonucleotide. Alternately, amino or thiol groups can be introduced during synthesis. These reactive groups are available for linking to essentially any fluorophore or enzyme using crosslinking reagents.

**RNA probes** RNA probes bind tighter to their complementary strands than do DNA probes. Poor stability due to ubiquitous ribonucleases has hampered more widespread use of short RNA probes, as has the difficulty of efficient chemical synthesis of long RNA oligomers. Recent advances in RNA synthetic chemistry have solved the latter problem.

Long RNA probes are generated by *in vitro* transcription from linearized plasmid DNA containing a promoter sequence for a DNA-dependent RNA polymerase such as SP3, T3, or T7 polymerases. Commercially available kits for high-yield transcription with label incorporation are available. It is also technically trivial to introduce a T7 promoter sequence as a 5'-extension of a PCR primer. Amplification introduces the promoter sequence into the amplicon. Transcription of the amplicon with T7 RNA polymerase and a modified NTP yields the labeled RNA probe. Shorter RNA probes (less than ~50 bases) are chemically synthesized, and label is most conveniently introduced during synthesis.

**Labeling immunoenzyme conjugates** Extensive publications describe methods to covalently link avidin or immunoglobulins to reporter enzymes. A wide range of bifunctional linkers are available commercially. Prepared, stabilized conjugates are available from immunological reagent suppliers.

## Limitations and Future Developments

The most significant limitation of immunochemical methods is inadequate sensitivity such that preamplification by PCR is required. Further improvements in solid phases, reporter enzymes, substrates, and hybridization probes will extend the range of analytes amenable to assay without amplification. Solid phases designed specifically for DNA immunoassays are needed. Enzyme engineering for thermostability,

lower background binding, and higher activity is possible with current technology. These advances could yield a new generation of reporter labels.

Triplex, quadruplex, and nucleic acid analog probes hold promise for assays of improved sensitivity and specificity. To date, limited use has been made of nucleic acid analogs as probes even though the advantages of some structural types for antisense therapeutics may extend to diagnostic applications. The use of such probes will increase specificity and sensitivity of probe hybridization assays.

Ultimately, immunochemical reagents of relatively low cost hold the key to rapid tests for DNA analysis without amplification.

### Introduction

Molecular technologies are currently evolving rapidly the biological sciences. This results in an immense progress in accumulation of new data potentially useful for molecular diagnostics. One of these highly sophisticated methodologies is the quantitative assessment of target nucleic acids, mostly performed as quantitative polymerase chain reaction (PCR) on DNA level or combined with reverse transcription PCR (RT-PCR) to investigate the transcriptome on RNA level. To quantify local tissue-specific expression even in tissues with low abundances, very sensitive methods are required, which allow reliable mRNA quantification. The aim of a full quantitative method is to estimate, as exact and reliable as possible, the number of target molecules in the sample. For this exact quantification of low abundant gene expression only a few PCR methods allow reliable mRNA quantification.

(A) Internally standardized competitive RT-PCR measured by high-performance liquid chromatography separation and ultraviolet detection or high-resolution

gel electrophoresis followed by densitometric analysis: in a competitive RT-PCR, a reference RNA mutant is reverse transcribed and coamplified in the same reaction tube with the native mRNA sequence of interest. Internally standardized RT-PCR is a very time consuming and laborious technique. It is generally believed to yield the most precise results, because all parameters throughout RT-PCR act on both the analyte and reference mutant.

(B) Externally standardized RT-PCR with online-detection using SYBR Green I technology: real-time RT-PCR with SYBR Green I detection produces sensitive and reliable results. Due to the use of an external standard curve, the amplification efficiencies for the calibration curve and the analyte must be equal for accurate quantification.

(C) Externally standardized RT-PCR with online-detection using specific hybridization probes: this detection format is based on various fluorescence detection formats, e.g., fluorescence resonance energy transfer (FRET).

(D) Array technologies in combination with real-time RT-PCR: microarray technology is a powerful technique in order to analyze the gene expression of thousands of genes (up to 20 000) in a short time. Problems encountered include inconsistent fidelity, high variability, sensitivity not sufficient for low abundant expressed genes, discrepancy in fold-changes calculation, and lack of specificity for different isoforms

### Introduction

Molecular technologies are currently evolving rapidly the biological sciences. This results in an immense progress in accumulation of new data potentially useful for molecular diagnostics. One of these highly sophisticated methodologies is the quantitative assessment of target nucleic acids, mostly performed as quantitative polymerase chain reaction (PCR) on DNA level or combined with reverse transcription PCR (RT-PCR) to investigate the transcriptome on RNA level. To quantify local tissue-specific expression even in tissues with low abundances, very sensitive methods are required, which allow reliable mRNA quantification. The aim of a full quantitative method is to estimate, as exact and reliable as possible, the number of target molecules in the sample. For this exact quantification of low abundant gene expression only a few PCR methods allow reliable mRNA quantification.

(A) Internally standardized competitive RT-PCR measured by high-performance liquid chromatography separation and ultraviolet detection or high-resolution

gel electrophoresis followed by densitometric analysis: in a competitive RT-PCR, a reference RNA mutant is reverse transcribed and coamplified in the same reaction tube with the native mRNA sequence of interest. Internally standardized RT-PCR is a very time consuming and laborious technique. It is generally believed to yield the most precise results, because all parameters throughout RT-PCR act on both the analyte and reference mutant.

(B) Externally standardized RT-PCR with online-detection using SYBR Green I technology: real-time RT-PCR with SYBR Green I detection produces sensitive and reliable results. Due to the use of an external standard curve, the amplification efficiencies for the calibration curve and the analyte must be equal for accurate quantification.

(C) Externally standardized RT-PCR with online-detection using specific hybridization probes: this detection format is based on various fluorescence detection formats, e.g., fluorescence resonance energy transfer (FRET).

(D) Array technologies in combination with real-time RT-PCR: microarray technology is a powerful technique in order to analyze the gene expression of thousands of genes (up to 20 000) in a short time. Problems encountered include inconsistent fidelity, high variability, sensitivity not sufficient for low abundant expressed genes, discrepancy in fold-changes calculation, and lack of specificity for different isoforms

or differentially expressed genes. The DNA microarray based screening of tissue-specific gene expression and confirmation of putative candidate target genes by kinetic RT-PCR represents a powerful and optimal combination. Hereby, the advantages of both quantification systems can be added – the high throughput capacity of the microarray as well as sensitivity and specificity of the real-time RT-PCR.

Because of its high sensitivity, RT-PCR is being increasingly applied to quantify physiologically relevant changes in gene expression. RT-PCR has a detection limit 10- to 100-fold better than other methods, e.g., RNA-protection-assay or Northern-hybridization. It offers a new dimension in the detection of rare RNA by amplifying a single-stranded cDNA after reverse transcription. Today real-time RT-PCR (qRT-PCR or kinetic RT-PCR) is increasingly used because of its high sensitivity, good reproducibility, and wide dynamic quantification range. The first practical kinetic PCR technology, the 5'-nuclease assay, was established in 1993 and combines the exponential PCR amplification of a specific transcript with the monitoring of newly synthesized DNA in each performed PCR cycle. It is the most sensitive method for the detection and quantification of gene expression levels, in particular for low abundant transcripts in tissues with low RNA concentrations, from limited tissue samples, and for the elucidation of small changes in mRNA expression levels. While kinetic RT-PCR has a tremendous potential for analytical and quantitative applications, a comprehensive understanding of its underlying

principles is important. Fidelity of real-time RT-PCR is associated with its true specificity, sensitivity, reproducibility, robustness, and as a fully reliable quantitative method. It suffers from the problems inherent in RT and PCR. This review analyzes the possibilities and problems in mRNA quantification analytics.

RNA Isolation and cDNA Synthesis

The integrity of purified RNA is critical to all gene expression analysis techniques. For successful and reliable diagnostic use, real-time RT-PCR needs high quality, DNA-free, and undegraded RNA. Accurate quantification and quality assessment of the starting RNA sample is particularly important for absolute quantification methods that normalize specific mRNA expression levels against total RNA ('molecules per gram total RNA' or 'transcript concentrations per gram total RNA'). The source of RNA, sampling techniques (biopsy material, single cell sampling, laser microdissection) as well as RNA isolation techniques (either total RNA or poly-adenylated RNA isolation techniques) often vary significantly between processing laboratories. In Figure 1 the transcriptome of various tissue total RNA is characterized and all subfractions are described. As shown, most genes are transcribed at very low abundant mRNA levels under 20 copies per cell. Therefore, highly sensitive quantification methods are necessary to perform a precise and reliable quantification of low abundant genes, e.g., cytokines, growth factors, hormones, their corresponding receptors, and enzymes.

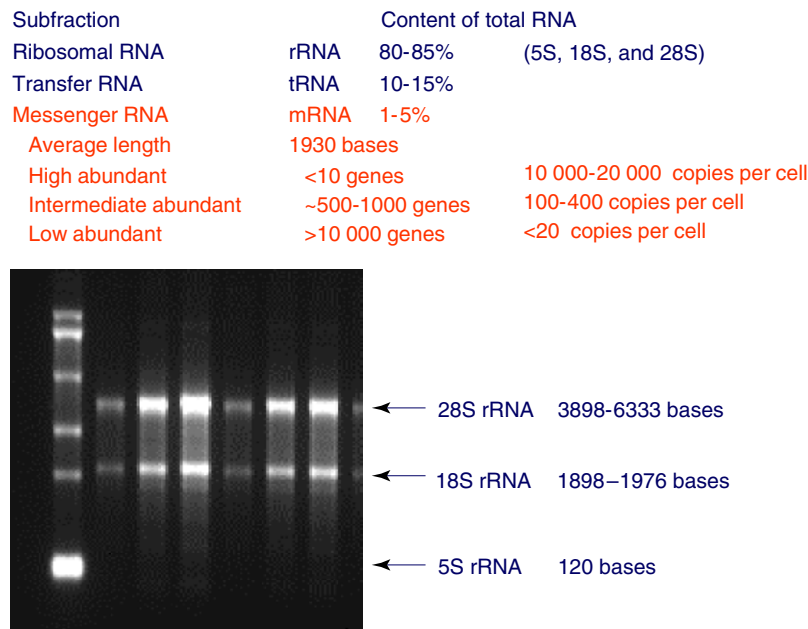

Figure 1 Characterization of the transcriptome isolated from numerous tissue samples.

Isolated RNA may contain tissue enzyme inhibitors and genomic DNA that result in reduced RT and PCR reaction efficiencies and generate unreliable and wrong quantification results. While this is not a problem for some applications, the tremendous amplification power of kinetic PCR may result in even the smallest amount of DNA contamination interfering with the desired specific amplification. To confirm the absence of residual DNA, a minus-RT should be included. Additionally it may be necessary to treat the RNA sample with commercially available RNase-free DNase, to get rid of residual DNA. Furthermore, the design of the PCR product should incorporate at least one exon to exon splice junction to allow a product obtained from the cDNA to be distinguished from genomic DNA contamination.

A further important step in quantitative RT-PCR is the production of a single-stranded (ss) complementary DNA copy (cDNA) of the RNA through the reverse transcriptase (RT). Its dynamic range, sensitivity, and specificity are of prime consideration for a successful kinetic RT-PCR assay. For many quantitative applications, moloney murine leukaemia virus (MMLV) H<sup>-</sup> RT is the enzyme of choice, as its cDNA synthesis rate is up to 50-fold greater than that of avian myeloblastosis virus (AMV). Newly available thermostable enzymes maintain their activity up to 70°C, thus permitting increased specificity and efficiency of first primer annealing. However, this enzyme type may be less robust than more conventional ones as it appears to be more sensitive to inhibitors present in RNA preparation.

The RT step is the source of most of the variability in a kinetic RT-PCR experiment and for each enzyme, the specific reaction conditions has to be optimized. It cannot be assumed that different reactions have the same cDNA synthesis efficiency. Therefore, the result can be high variability during multiple RT reactions. To circumvent this high interassay variations in RT, target gene unspecific primers, e.g., random-hexamer, -octamer, or -decamer primers, can be used and a cDNA pool can be synthesized. Similarly, poly-T oligo-nucleotides can anneal to the polyadenylated 3'-(poly-A) tail found on most mRNA. Therefore, the gene expression results are directly comparable between the applied assays, at least within one RT pool. In conclusion, a rank order of RT efficiency can be shown for the applied different primers for one specific gene: random hexamer primers > poly-dt primer > gene specific primer. Importantly, not only RNA quantity and quality, but also yield and quality of cDNA can be highly variable. Certainly, there is evidence that cDNA yield from sequences near the 5'-end of partially degraded mRNA is significantly less than from sequences near

the poly-A tail, and assays aimed at identifying RNA degradation are being developed. Thus, reliable internal quality control of cDNA synthesis is essential. Controls are generally performed by PCR amplification of reference genes, mostly common housekeeping genes (GAPDH, albumin, actins, tubulins, cyclophilin, microglobulins, 18S or 28S rRNA). The reference genes used as well as the expression levels vary between different laboratories, and only few of them have been critically evaluated.

## Real-Time RT-PCR Reaction Kinetics

The efficacy of kinetic RT-PCR is measured by its specificity, low background fluorescence, steep fluorescence increase and high amplification efficiency, and high level plateau. Typically the PCR can be divided into four characteristic phases (Figure 2):

- first phase is hidden under the background fluorescence, where an exponential amplification is expected;
- second phase with exponential amplification, that can be detected above the background;
- third phase with linear amplification efficiency and a steep increase of fluorescence;
- fourth phase or plateau phase, defined as the attenuation in the rate of exponential product accumulation, which is seen concomitantly in later cycles;

The amount of amplified target is directly proportional to the input amount of target, only during the exponential phase of PCR amplification. Hence, the key factor in the quantitative ability of kinetic RT-PCR is that it measures the product of the target gene within that phase. Since data acquisition and analysis are performed in the same tube, this increases sample throughput, reduces carryover contamination, and removes post-PCR processing as a potential source of error. In contrast, during the plateau phase of the

**Figure 2** The four characteristic phases of PCR, evaluated by real-time PCR fluorescence acquisition.

PCR there is no direct relation of DNA input to amplified target; hence classical RT-PCR assays have to be stopped at least in linear phase. The exponential range of amplification has to be determined for each transcript empirically by amplifying equivalent amounts of cDNA over various cycles of the PCR or by amplifying dilutions of cDNA over the same number of PCR cycles.

## Chemistry Developed and Real-Time RT-PCR Platforms

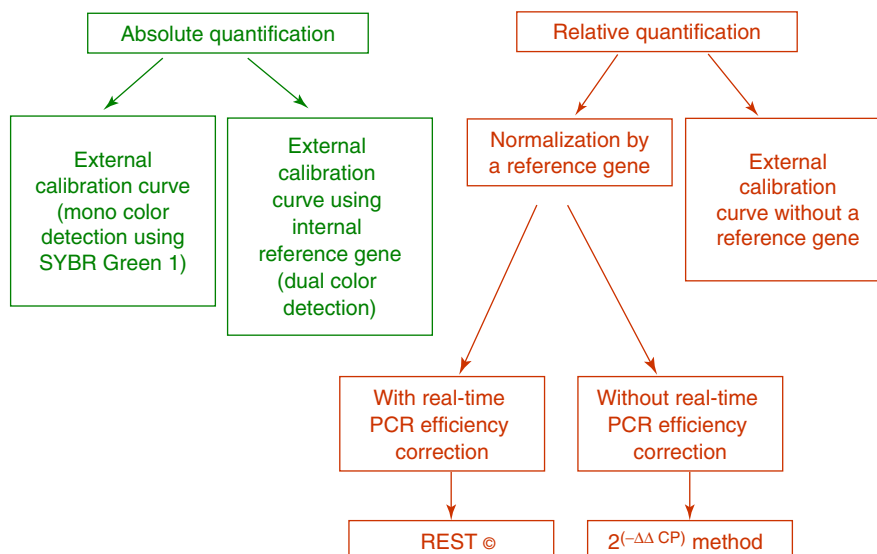

Two general methods for the quantitative detection of the amplicon became established: specific double-strand (ds) DNA binding agents or gene specific fluorescent probes, e.g., based on FRET. The best-known probe-based system is ABI TaqMan, which makes use of the 5'-exonuclease activity of Taq polymerase to quantify target sequences in the samples. Probe hydrolysis separates fluorophore and quencher and results in an increased fluorescence signal, called FRET. The alternative is a nonsequence specific fluorescent intercalating ds DNA binding dye, e.g., SYBR Green I (Molecular Probes). For single PCR product reactions with well-designed primers, SYBR Green I can work extremely well, with spurious nonspecific background only showing up in very late cycles. Among the real-time detection chemistry, SYBR Green I and TaqMan assays produced comparable dynamic range and sensitivity, while SYBR Green I detection was more precise and produced a more linear decay plot than the TaqMan probe detection.

The PCR machines differ in sample capacity, up to 96- and 384-well standard format, others process 72

samples or require 32 specialized glass capillaries, excitation method (lasers, others broad spectrum light sources with various filters), and fluorescence acquisition channels. There are also platform-specific differences in how the software processes data with focus on absolute or relative quantification strategies. For at least two systems and chemistries, the ABI PRISM 7700 using TaqMan Probes and Roche's LightCycler using Hybridisation Probes, there is little difference in accuracy and performance.

## Quantification Strategies in qRT-PCR

Two general quantification strategies can be performed in qRT-PCR: the levels of expressed genes may be measured by absolute or relative quantitative real-time RT-PCR (Figure 3). Absolute quantification relates the PCR signal to input copy number using a calibration curve, while relative quantification measures the relative change in mRNA expression levels. The reliability of an absolute real-time RT-PCR assay depends on the condition of identical amplification efficiency (see the section 'Real-Time PCR Amplification Efficiency') for both the native target and the calibration curve in RT reaction and in following kinetic PCR. Nowadays, a relative quantification is easier to perform than absolute quantification because there is no need for a calibration curve. It is based on the expression levels of a target gene versus a housekeeping gene and in theory is adequate for most purposes in animal sciences to investigate physiological changes in gene expression levels. The units used to express relative quantities are irrelevant, and the relative quantities can be compared across multiple real-time RT-PCR experiments.

**Figure 3** Quantification strategies in real-time PCR (<http://www.wzw.tum.de/gene-quantification/optimization.html>).

## Absolute Quantification

Calibration curves allow the generation of highly specific, sensitive, and reproducible data. However, the external calibration curve model has to be thoroughly validated as the accuracy of absolute quantification in real-time RT-PCR depends entirely on the accuracy of the standard material. Standard design, production, determination of the exact standard concentration, and stability over long storage time is not straightforward and can be problematic. The dynamic range of the calibration curve performed can be up to nine orders of magnitude from  $<10^1$  to  $>10^{10}$  start molecules, depending on the applied purity of the standard material. The calibration curves used in absolute quantification can be based on known concentrations of DNA standard molecules, e.g., recombinant plasmid DNA (recDNA), *in vitro* transcribed recombinant RNA (recRNA), genomic DNA, RT-PCR product, and commercially synthesized big oligo-nucleotide. Stability and reproducibility in kinetic RT-PCR depends on the type of standard used. Cloned recDNA and genomic DNA are very stable and generate highly reproducible standard curves even after a long storage time, in comparison to freshly synthesized recRNA standard material. DNA based calibration curves are subject to the PCR step only, unlike the unknown mRNA samples that must first be reverse transcribed. This increases the potential for variability of the RT-PCR results and the amplification results may not be strictly comparable with the results from the unknown samples. However, the problem of sensitivity of the RT-PCR to small variations in the reaction setup is always lurking in the background as a potential drawback to this simple procedure. Therefore, quantification with external standards requires careful optimization of its precision (replicates in the same kinetic RT-PCR run – intraassay variation) and reproducibility (replicates in separate kinetic RT-PCR runs – interassay variation) in order to understand the limitations within the given application.

A recRNA standard that was synthesized *in vitro* from a cloned RT-PCR fragment in plasmid DNA is one option. However, identical RT efficiency, as well as real-time PCR amplification efficiencies for calibration curve and target cDNA will have to be tested and confirmed, if the recDNA is to provide a valid standard for mRNA quantification. This is because only the specific recRNA molecules are present during RT and the kinetics of cDNA synthesis are not like those in native RNA (the unknown sample) that also contain a high percentage of natural occurring subfractions (Figure 1). These missing RNA

subfractions can influence the cDNA synthesis rate and in consequence RT efficiency rises and calibration curves are then overestimated in gene quantification. To compensate for background effects and mimic a natural RNA distribution, like in native total RNA, total RNA isolated from bacterial, insect cell lines, poly-A RNA or tRNA can be added.

No matter how accurately the concentration of the standard material is known, the final result is always reported relatively compared to a defined unit of interest: e.g., copies per defined nanograms of total RNA, copies per genome (6.4 pg DNA), copies per cell, copies per gram of tissue, copies per milliliter of blood, etc. If absolute changes in copy number are important then the denominator still must be shown to be invariable across the comparison. The quality of gene quantification data cannot be better than the quality of the denominator itself. Any denominator variation will obscure real changes and produce artificial changes and wrong quantification results. Careful use of controls is critical to demonstrate that the choice of denominator was a wise one.

External standard quantification is the method of choice for the nucleic acid quantification, independent of any hardware platform used. The specificity, sensitivity, linearity, and reproducibility allow absolute and accurate quantification of molecules even in tissues with low mRNA abundance ( $<100$  mRNA molecules) and a detection down to a few molecules ( $<10$  mRNA molecules). The dynamic range of an optimally validated and optimized external standardized real-time RT-PCR assay can accurately detect target mRNA up to nine orders of magnitude or a billion-fold range with high assay linearity ( $r > 0.99$ ). In general a mean intraassay variation of 10–20% and a mean interassay variation of 15–30% on molecule basis (maximal 2–4% variability on crossing point (CP) basis) is realistic over the wide dynamic range, as shown for estrogen receptor (ER) kinetic RT-PCR (Figure 4). At high ( $>10^7$ ) and low ( $<10^3$ ) template copy input levels, the assay variability is higher than in the range between the two. At very low copy numbers, under 20 copies per tube, the random variation due to sampling error (Poisson's error law) becomes significant.

## Relative Quantification

Relative quantification determines the changes in steady-state mRNA levels of a gene across multiple samples and gives a result relative to the levels of an internal control RNA. This reference gene is often a housekeeping gene and can be coamplified in the same tube in a multiplex assay or can be amplified in a separate tube (Figure 3). Therefore, relative

**Figure 4** Mean intraassay ( $n = 7 \times 3$ ) and interassay variation ( $n = 7 \times 7$ ) of estrogen receptor (ER) alpha real-time RT-PCR assay, using externally standardized recDNA calibration curve.

quantification does not require standards with known concentrations and the reference can be any transcript, as long as its sequence is known. Relative quantification is based on the expression levels of a target gene versus a reference gene and in many experiments is adequate for investigating physiological changes in gene expression levels. To calculate the expression of a target gene in relation to an adequate reference gene, various mathematical models are established. Calculations are based on the comparison of the distinct cycle determined by various methods, e.g., CP or threshold values (Ct) at a constant level of

fluorescence; or CP acquisition according to established mathematic algorithm. To date several mathematical models have been developed, which calculate the relative expression ratio. Relative quantification models without efficiency correction are available and published (eqns [1] and [2]).

$$R = 2^{-(\Delta CP_{\text{sample}} - \Delta CP_{\text{control}})} \quad [1]$$

$$R = 2^{-\Delta \Delta CP} \quad [2]$$

More recently developed mathematical models with kinetic PCR efficiency correction allow for a more

precise quantification of the relative expression levels (eqns [3] and [4]).

$$\text{ratio} = \frac{(E_{\text{target}})^{\Delta\text{CP}_{\text{target}}(\text{control}-\text{sample})}}{(E_{\text{ref}})^{\Delta\text{CP}_{\text{ref}}(\text{control}-\text{sample})}} \quad [3]$$

$$\text{ratio} = \frac{(E_{\text{target}})^{\Delta\text{CP}_{\text{target}}(\text{mean control}-\text{mean sample})}}{(E_{\text{ref}})^{\Delta\text{CP}_{\text{ref}}(\text{mean control}-\text{mean sample})}} \quad [4]$$

The relative expression ratio of a target gene is computed, based on its calculated real-time PCR efficiencies ( $E$ ) and the CP difference ( $\Delta\text{CP}$ ) of one unknown sample (treatment) versus one control ( $\Delta\text{CP}_{\text{control}-\text{treatment}}$ ). Using relative expression software tool (REST) the relative calculation procedure is based on the mean CP of the experimental groups (eqn [4]). In these models, the target gene expression is normalized by a nonregulated reference gene expression, e.g., derived from classical and frequently described housekeeping genes. The crucial problem in this relative approach is the most common reference gene transcripts from the so-called housekeeping genes, whose mRNA expression can be regulated and whose levels vary significantly with treatment or between individuals. However, relative quantification can generate useful and biologically relevant information when used appropriately.

### Real-Time PCR Amplification Efficiency

Individual samples generate different and individual fluorescence histories in kinetic RT-PCR. The shapes

of amplification curves differ in the steepness of any fluorescence increase and in the absolute fluorescence levels at plateau depending on background fluorescence levels. The PCR efficiency has a major impact on the fluorescence history and the accuracy of the calculated expression result and is critically influenced by PCR reaction components. A correction for efficiency, as performed in efficiency corrected mathematical models, is strongly recommended, which results in a more reliable estimation of the real expression ratio compared to no efficiency correction. Small efficiency differences between target and reference gene generate false expression ratio, resulting in over- or underestimation of the real initial mRNA amount. Therefore, efficiency corrected quantification corrections should be included in the automation and calculation procedure in relative quantification models. Several methods are described in the literature or were developed to calculate real-time PCR efficiency.

(A) Efficiency calculation from the slopes of the calibration curve, according to the equation:  $E = 10^{(-1/\text{slope})}$  (Figure 5). Efficiency vary with high linearity ( $r > 0.95$ ) from  $E = 1.60$  to maximal values up to  $E = 2.10$ . Typically, the relationship between CP and the logarithm of the starting copy number of the target sequence should remain linear for up to four orders of magnitude. This calculation method results, in some cases, in efficiencies higher than ( $E > 2.0$ ), which is practically impossible in the PCR

**Figure 5** Determination of real-time PCR efficiencies from the slopes of the calibration curve (method A), according to the equation:  $E = 10^{(-1/\text{slope})}$  of reference gene glutathione transferase (Gst), and two 'target genes': tryptophan operon (TyrA) and aspartate transcarbamylase (PyrB). CP cycles versus cDNA concentration input (log scale) were plotted to calculate the slope (mean  $\pm$  SD;  $n = 3$ ).

amplification theory. This probably indicates that this efficiency calculation method is not optimal and overestimates the real efficiency.

(B) Efficiency calculation from the fluorescence increases in third linear phase (Figure 2 or at first derivate maximum (FDM) Figure 6) of each logarithmic fluorescence history plot. The investigator has to decide which cycle number to include in the analysis and plot a linear regression, where the slope of the regression line represents the PCR efficiency. Here efficiencies between  $E = 1.35$  and  $E = 1.60$  are found, which differ dramatically from the results above. This efficiency calculation method might underestimate the real efficiency, because data evaluation is made in linear phase near the plateau, where reaction efficiency gets restrictive.

(C) Efficiency calculation on the basis of all fluorescence data points (starting at first cycle to the last cycle), according to a sigmoidal or logistic curve fit model. The advantage of such model is that all data points will be included in the calculation process. No background subtraction is necessary. Slope value is only measured at the point of inflexion at absolute maximum fluorescence increase of FDM and therefore nearly identical to method B ( $1.35 < E < 1.60$ ). This method is easy to perform and a good estimator for the maximum curve slope with high correlation coefficient ( $r > 0.99$ ) and level of significance ( $p < 0.001$ ).

(D) Efficiency calculation from the fluorescence increase only in the second real exponential phase,

according to a polynomial curve fit, as described earlier  $Y_n = Y_0(E)^n$ , where  $Y_n$  is fluorescence acquired at cycle  $n$ , and  $Y_0$  initial fluorescence, so called ground fluorescence. This phase around the second derivate maximum (SDM) exhibit a real exponential amplification behavior (Figure 6). Here, in the exponential part, the PCR reaction kinetic is still under full enzymatic activity with no restrictions. In this method the calculation is performed on each reaction kinetic plot and the amplification efficiency can be determined exactly. They range from  $E = 1.75$  to  $E = 1.90$ , hence are between the other methods.

Which efficiency calculation method is the best or correct one and which one shows the realistic real-time PCR kinetic, and thereby is highly reproducible, has to be evaluated in further trials.

## Normalization of Expression Results

The reliability of any relative RT-PCR experiment can be improved by including an invariant endogenous control in the assay to correct for sample to sample variations in RT-PCR efficiency and errors in sample quantification. A biologically meaningful reporting of target mRNA copy numbers requires accurate and relevant normalization to some standard and is strongly recommended. But the quality of normalized quantitative expression data cannot be better than the quality of the normalizer itself. Any variation in the normalizer will obscure real changes

**Figure 6** Plot of fluorescence observations from LightCycler (Roche Diagnostics). Forty observations give a sigmoid trajectory that can be described by full data fit (four-parametric logistic model). Ground phase can be linearly well regressed. FDM and SDM denote position of FDM and SDM within full data fit.

and produce artificial changes. Real-time RT-PCR-specific errors in the quantification of mRNA transcripts are easily compounded with any variation in the amount of starting material between the samples, e.g., caused by sample-to-sample variation, variation in RNA integrity, RT efficiency differences, and cDNA sample loading variation. This is especially relevant when the samples have been obtained from different individuals, different tissues, and different time courses, and will result in the misinterpretation of the derived expression profile of the target genes. Therefore, normalization of target gene expression levels must be performed to compensate intra- and interkinetic RT-PCR variations. Data normalization can be carried out against an endogenous unregulated reference gene transcript or against total cellular DNA or RNA content (molecules per gram total DNA/RNA and concentrations per gram total DNA/RNA). Normalization according to the total cellular RNA content is increasingly used, but little is known about the total RNA content of cells or even about the mRNA concentrations. The content per cell or per gram tissue may vary in different tissues (*in vivo*), in cell culture (*in vitro*), between individuals, and under different experimental conditions. Nevertheless, it has been shown that normalization to total cellular RNA is the least unreliable method. It requires an accurate quantification of the isolated total RNA or mRNA fraction. Alternatively, the rRNA content has been proposed as an optimal and stable basis for normalization, despite reservations concerning its expression levels, transcription by a different RNA polymerase, and possible imbalances in rRNA and mRNA fractions between different samples.

Commonly used housekeeping genes may be suitable for reference genes, since they are present in all nucleated cell types and are necessary for basic cell survival. The mRNA synthesis of housekeeping genes is considered to be stable in various tissues, even under experimental treatments. However, numerous treatments and studies have already shown that the above-mentioned housekeeping genes are regulated and vary under experimental conditions. It remains up to the individual investigator to choose a reference gene that is best for reliable normalization in their particular experimental setting. It has to be emphasized again, that the choice of housekeeping or lineage specific genes is critical.

Today, there is increasing appreciation of a more reliable normalization in relative quantification. It is vital to develop universal, artificial, and stable, internal standard materials that can be added prior to the RNA preparation to monitor the efficiency of RT as well as the kinetic PCR. Usually more than one housekeeping gene should be tested in a multiple

correlation analysis and its behavior summarized to a housekeeping gene index. According to this index, which is based on the weighted expression of at least three housekeeping genes, a more reliable basis of normalization in relative quantification can be postulated. Recently the software tool GeNorm was established for the evaluation of housekeeping genes expression levels. GeNorm allows for an accurate normalization of real-time quantitative RT-PCR data by geometric averaging of multiple internal control genes (<http://allserv.rug.ac.be/~jvdesomp/genorm/>). The normalization strategy used in GeNorm is a prerequisite for accurate kinetic RT-PCR expression profiling, which opens up the possibility of studying the biological relevance of small expression differences.

## Data Processing

After performing qRT-PCR, a reliable data evaluation is next. The calculation unit in real-time PCR is a sample specific and characteristic CP. For CP determination, various fluorescence acquisition methodologies are possible. The Fit Point Method and Threshold Cycle Method measure the CP at a constant fluorescence level. These constant threshold methods assume that all samples have the same cDNA concentration at the point where the fluorescence signal significantly increases in second to third phase over the background fluorescence (Figure 2). Measuring the level of background fluorescence can be a challenge in real-time PCR reactions with significant background fluorescence variations, caused by drift-ups and drift-downs over the course of the reaction. Averaging over a drifting background will give an overestimation of variance and thus increase the threshold level. The threshold level can be calculated by fitting the intersecting line upon the 10-times value of ground fluorescence standard deviation. This acquisition mode can be easily automated and is very robust. In the Fit Point Method, the user discards the uninformative background points, excludes the plateau values by entering the number of log-linear points, and then fits a log line to the linear portion of the amplification curves. These log lines are extrapolated back to a common threshold line and the intersection of the two lines provides the CP value. The strength of this method is its extreme robustness. The weakness is that it cannot be easily automated and requires a lot of user input. Fit Point Method or Threshold Cycle Method can be used on all available platforms with different evaluation of background variability.

The problems of defining a constant background for all samples within one run, sample-to-sample

differences in variance and absolute fluorescence values lead to develop a new acquisition modulus according to mathematical algorithms. In the LightCycler or in Rotor-Gene software packages, the SDM are performed where CP is automatically identified and measured at the maximum acceleration of fluorescence. The amplification reaction and the kinetic fluorescence history over various cycles is obviously not a smooth and easy function. It is possible to fit sigmoidal- and polynomial-curve models, with high significance ( $p < 0.001$ ) and coefficient of correlation ( $r > 0.99$ ), which can be differentiated and the SDM can be estimated. This increase in the rate of fluorescence increase, or better called the acceleration of the fluorescence signal, slows down at the beginning of the third linear phase. Therefore, the cycle where the SDM is always between the second exponential and third linear phase.

Nevertheless, successful application of real-time RT-PCR depends on a clear understanding of the practical problems. Therefore, a coherent experimental design, application, and validation of the individual real-time RT-PCR assay remain essential for accurate and complete quantitative measurement of mRNA transcripts.

### Introduction

Optical spectroscopy may be defined as covering that portion of the electromagnetic spectrum (EMS) from 100 nm in the vacuum ultraviolet (UV) to 20 000 nm in the infrared. The relative position of optical spectroscopy within the entirety of the EMS is shown in **Figure 1**.

Essentially the spectroscopic information in this region arises from atomic and molecular transitions involving both inner and outer electrons together with vibrational transitions and rotational fine structure. In principle, the spectroscopic processes of emission, absorption, luminescence, and scattering should all be covered. Within the scope of these four topics, discussion will be confined to the UV–visible (absorption and fluorescence), the near-infrared

(NIR), and infrared (IR). Aspects of atomic spectroscopy and scattering are covered elsewhere, as are polarization and related effects.

### Overview of Radiation Sources

Ideal spectroscopic sources should have a uniform high-energy output over a wide wavelength range and be stable over long periods of time. In practice, sources show marked wavelength dependence of intensity although most sources are intrinsically stable provided that their power sources are stable.

Broadly speaking spectroscopic sources may be classified into two types: broad band or continuum sources for absorption work and narrow band or line sources for emission work. The latter category is dealt with under atomic emission spectrometry. Laser sources find their greatest application in Raman spectroscopy and will not be covered here. The continuum sources subdivide into two further categories: thermal and arc sources. The arc sources are of higher energy and are primarily used in the UV range and for fluorescence work. The thermal sources are blackbody radiators and cover the majority of the spectral region 300–20 000 nm. For this reason, the underlying theory to blackbody radiation will be dealt with in more detail later.

**Figure 1** The electromagnetic spectrum. (Reproduced with permission from Thorne AP (1998) *Spectrophysics* 2nd edn. London: Chapman and Hall.)

## Arc Sources

These sources operate on the principle that an electric discharge through a suitable ionized gas results in a continuum spectrum. The majority of this energy lies within the UV region of the spectrum,  $\sim 100\text{--}300\text{ nm}$ .

### High-Pressure Arc Sources

These sources are constructed in the following way. A quartz envelope, containing an inert gas, usually xenon at pressures up to several atmospheres, has an arc struck between a tungsten anode, and cathode. The arc requires high powers of 500 W or more. These sources find the majority of their application in fluorescence work where the signal output is directly proportional to input intensity of the source. Pulsed sources have been used for the vacuum UV although high-intensity a.c. arcs are available in more modern instruments (Figure 2).

### Low-Pressure Arcs

Much lower powers are required in absorption work where the transmittance is a ratio of the input intensity to the transmitted intensity of the beam. For this reason, the much lower powered deuterium arc is the source of choice in the UV.

Its power requirements are much more modest,  $\sim 30\text{ W}$ , and a continuum from  $\sim 180\text{--}350\text{ nm}$  is available (Figure 3). An added advantage is that at lower energies in the visible region, the lamp becomes a line source yielding two strong lines at the 486.1 and 656.3 nm, which are useful for wavelength calibration purposes.

A more recent innovation of low-pressure xenon arcs which use pulsed power supplies allows much increased spectral output. The advantage is that the peak power output can be as high as 40 kW but since the pulse width is  $\sim 1\text{ }\mu\text{s}$ , the average power consumption

**Figure 2** Typical high-pressure arc lamps. (A) 150 W xenon lamp, (B) 200 W mercury lamp. Dimensions in mm. (Reproduced with permission from Knowles A and Burgess C (1984) *Practical absorption spectrometry*. Ultraviolet Spectrometry Group. London: Chapman and Hall.)

may be less than 5 W. Ozone health and safety issues with high-pressure arcs are absent. The spectral distributions of such lamps approximate to blackbody emitters of 10 000 K or more. A typical spectral output from such a source is shown in Figure 4.

## Blackbody Radiation

An ideal blackbody exhibits perfect emission and absorption of energy at all wavelengths and at all angles. The total radiant energy of such a body is a function only of its temperature. This ideal is shown in Figure 5.

**Figure 3** Typical deuterium low-pressure arc lamp, dimensions in mm. (Reproduced with permission from Knowles A and Burgess C (1984) *Practical absorption spectrometry*. *Ultraviolet Spectrometry Group*. London: Chapman and Hall.)

**Figure 4** Typical spectral output from a low-pressure pulsed xenon source. (Reproduced with permission from Knowles A and Burgess C (1984) *Practical absorption spectrometry*. *Ultraviolet Spectrometry Group*. London: Chapman and Hall.)

In practice, few surfaces closely approach blackbody behavior, e.g., carbon black, platinum black, gold black, and carborundum. However, a small

**Figure 5** Idealized blackbody cavity radiator. From Grum and Becherer (1979).

aperture in a blackbody cavity can closely approximate to a true blackbody source. The differences in behavior of any thermal radiator and ideal blackbody behavior can be described in terms of emissivity, absorptance, and reflectance parameters (Kirchhoff's Law).

The following is a short description of blackbody behavior. For a more detailed explanation see Grum and Becherer (1979). Throughout this section the following symbols will be used:

$c$  = speed of light ( $2.998 \times 10^{-8} \text{ m s}^{-1}$ ),  
 $\nu$  = frequency of the radiation in Hz,  
 $\lambda$  = wavelength of the radiation in m,  
 $h$  = Planck's constant ( $6.626 \times 10^{-34} \text{ J s}$ ),  
 $K$  = temperature in K, and  
 $k$  = Boltzmann's constant ( $1.381 \times 10^{-23} \text{ J K}^{-1}$ )

The average spectral energy density in a blackbody cavity radiator,  $\bar{\omega}_\nu$ , is given in eqn [1].

$$\bar{\omega}_\nu = \left[ \frac{8\pi\nu^2}{c^3} \right] \left[ \frac{h\nu}{e^{h\nu/kT} - 1} \right] \text{ J m}^{-3} \text{ Hz}^{-1} \quad [1]$$

This equation is expressed in terms of frequency as opposed to wavelength. Using the following relationships:

$$\begin{aligned} \bar{\omega}_\nu d\nu &= \bar{\omega}_\lambda d\lambda \\ c &= \nu\lambda \\ d\lambda &= -\frac{c}{\nu^2} d\nu \end{aligned} \quad [2]$$

it can be shown that the equivalent average spectral energy density in terms of wavelength,  $\bar{\omega}_\lambda$ , is given by

$$\bar{\omega}_\lambda = \frac{8\pi hc}{\lambda^5} \frac{1}{e^{h\nu/kT} - 1} \text{ J m}^{-3} \text{ nm}^{-1} \quad [3]$$

It is important to note that  $\bar{\omega}_\lambda \neq \bar{\omega}_\nu$ .

Given a very small aperture in the side of the cavity which does not change the energy distribution within

it, we can now find the radiant power,  $M_\lambda$  from

$$M_\lambda = \pi \frac{c}{4\pi} \bar{\omega}_\lambda \quad [4]$$

where the factor  $c/4\pi$  represents the integrated radiance from  $4\pi$  steradians at any point in the cavity.

We can re-express this in terms of eqn [4] as

$$M_\lambda = \frac{2\pi hc^2}{\lambda^5} \frac{1}{e^{h\nu/kT} - 1} \text{ W m}^{-3} \text{ nm}^{-1} \quad [5]$$

This is the key relationship and is the Planck black-body radiation equation. Integration of this equation over all wavelengths yields the total radiant exitance of a blackbody.

Rearranging eqn [5] and integrating we obtain

$$M_\lambda = 2\pi hc^2 \int_0^\infty \frac{\lambda^{-5}}{e^{h\nu/kT} - 1} d\lambda \quad [6]$$

which may be solved by substitution of

$$x = \frac{hc}{\lambda kT}$$

so that

$$\lambda = \frac{hc}{xkT} \quad \text{and} \quad d\lambda = -\frac{hc}{x^2 kT} dx \quad [7]$$

and eqn [6] becomes

$$M_\lambda = \left(\frac{2\pi h}{c^2}\right) \left(\frac{kT}{h}\right)^4 \int_0^\infty \frac{x^3}{e^x - 1} dx \quad [8]$$

Given that

$$\int_0^\infty \frac{x^3}{e^x - 1} dx = 6 \left(1 + \frac{1}{2^4} + \frac{1}{3^4} + \frac{1}{4^4} + \dots\right) = 6a \quad [9]$$

where  $a = 1.0823\dots$  this simplifies to

$$M_\lambda = \frac{12\pi^5 k^4}{15 h^3 c^2} T^4 = \sigma T^4 \quad [10]$$

This is the Stefan–Boltzmann law where the constant term  $\sigma$  is equal to  $5.67 \times 10^{-8} \text{ W m}^{-2} \text{ K}^{-4}$ .

If, on the other hand, we differentiate eqn [5] with respect to wavelength and set to zero we obtain

$$\lambda_{\max} T \approx \frac{hc}{5k} \approx 2.88 \times 10^6 \text{ nm K} \quad [11]$$

which enables the wavelength at which maximum spectral energy occurs to be calculated from the absolute temperature. Note that the exact solution is

$$\lambda_{\max} T = \frac{hc}{4.96511\dots k}$$

This is the Wein displacement law.

The output of a blackbody for a given temperature is shown graphically in **Figure 6** by direct substitution in eqn [5]. Note that the position of maximum

**Figure 6** Emission from a perfect blackbody radiator calculated from eqn [5].

spectral output  $\lambda_{\max}$ , is given by eqn [11] and increases with decreasing temperature.

For practical situations where the system is not *in vacuo* eqn [11] is modified to be

$$n\lambda_{\max} T \approx 2.88 \times 10^6 \text{ nm K} \quad [12]$$

where  $n$  is the refractive index of the medium. Similarly the Stefan–Boltzmann law [10] becomes

$$M_\lambda = n^2 \sigma T^4 \quad [13]$$

This arises from the fact that the speed of light is a function of the density of the medium through which it travels.

## Thermal Sources for the Visible and NIR

The most commonly used thermal source for the visible and NIR is the tungsten filament lamp and its derivative the quartz halogen lamp (**Figure 7**). The tungsten lamp approximates to a 3000 K blackbody radiator below 1000 nm but shows considerable deviation above. Strictly speaking, it is more correct to use the term graybody radiator as in the visible region it exhibits an emissivity of 0.422 that is wavelength independent but the power output is not Planckian. Typical spectral outputs are shown in **Figure 8**.

**Figure 7** Tungsten sources. (A) Tungsten filament lamp, and (B) tungsten-halogen lamp, dimensions in mm. Reproduced with permission from Knowles A and Burgess C (1984) *practical absorption spectrometry*. Ultraviolet Spectrometry Group. London: Chapman and Hall.

## Thermal Sources for the IR and Far-IR

One of the earliest sources was the Nernst filament. This is a mixture of rare earth oxides, primarily of zirconium, made into rods 20–50 mm in length and 1–2.5 mm in diameter. These are fired at 1800°C and have platinum wire connections at both ends. The resultant output at 1800–2000°C is approximately blackbody. However, while relatively cheap to produce these have a very unpredictable life and are very sensitive to environmental factors including draughts. Refractory coated platinum-rhodium wire has been used as a more robust solution but is very expensive.

The Globar is a carborundum rod which gives excellent performance at ~1200°C and is much more reliable than the Nernst glower.

**Figure 8** Typical spectral outputs from a variety of sources. (Reproduced with permission from Knowles A and Burgess C (1984) *Practical absorption spectrometry*. Ultraviolet Spectrometry Group. London: Chapman and Hall.)

## Introduction

A fundamental distinction should be drawn between two main types of instrument employed in analytical spectrometry; namely nondispersive and dispersive optical arrangements. In the former instance, the instruments are called photometers and operate

primarily in the visible region and wavelength selection is by the use of a filter of some type. Dispersive instruments, on the other hand, are generally called spectrophotometers and employ a dispersive element, usually a prism or diffraction grating (plane or curved), to effect wavelength selection. The generic term for such an optical arrangement is a monochromator. Exceptionally, the dispersive element may be a curved diffraction grating arranged in conjunction with a solid-state detection system in the focal plane. This latter system is usually referred to as a polychromator. The whole subject of wavelength selection is very large indeed and this article will be

**Figure 7** Tungsten sources. (A) Tungsten filament lamp, and (B) tungsten-halogen lamp, dimensions in mm. Reproduced with permission from Knowles A and Burgess C (1984) *practical absorption spectrometry*. Ultraviolet Spectrometry Group. London: Chapman and Hall.

## Thermal Sources for the IR and Far-IR

One of the earliest sources was the Nernst filament. This is a mixture of rare earth oxides, primarily of zirconium, made into rods 20–50 mm in length and 1–2.5 mm in diameter. These are fired at 1800°C and have platinum wire connections at both ends. The resultant output at 1800–2000°C is approximately blackbody. However, while relatively cheap to produce these have a very unpredictable life and are very sensitive to environmental factors including draughts. Refractory coated platinum-rhodium wire has been used as a more robust solution but is very expensive.

The Globar is a carborundum rod which gives excellent performance at ~1200°C and is much more reliable than the Nernst glower.

## Introduction

A fundamental distinction should be drawn between two main types of instrument employed in analytical spectrometry; namely nondispersive and dispersive optical arrangements. In the former instance, the instruments are called photometers and operate

primarily in the visible region and wavelength selection is by the use of a filter of some type. Dispersive instruments, on the other hand, are generally called spectrophotometers and employ a dispersive element, usually a prism or diffraction grating (plane or curved), to effect wavelength selection. The generic term for such an optical arrangement is a monochromator. Exceptionally, the dispersive element may be a curved diffraction grating arranged in conjunction with a solid-state detection system in the focal plane. This latter system is usually referred to as a polychromator. The whole subject of wavelength selection is very large indeed and this article will be

able to present only a basic outline. A selection of more detailed works is given in Further Reading.

## Filters

Filters are categorized into three main groups: bandpass filters, edge filters, and neutral density filters.

The properties of each of the three main groups are summarized in **Table 1**. Strictly speaking, only bandpass filters are of direct relevance although blocking and attenuation filters are commonly used in optical spectroscopic instruments and are included for the sake of completeness. These properties are more easily assembled in diagrammatic form and typical transmittance–wavelength characteristics are shown in **Figure 1**. An example of a nominal 500 nm bandpass filter is shown in **Figure 1A**.

Edge filters are characterized by an abrupt change between the region of transmittance and the region of rejection. Long wavepass (LWP) filters reject shorter wavelengths and transmit longer wavelengths. The converse is true for short wavepass filters (SWP). By placing an LWP and SWP filter in series, the user can construct a variety of bandpass filters of varying bandwidths. However, except for specialized work, it is more usual to purchase a tailor-made bandpass filter. Commercial bandpass filters are available for wavelengths between 200 and 15 000 nm with bandwidths of between 0.1 nm and several thousand nm. Applications for bandpass filters include spectral radiometry, medical diagnostics, chemical analyses, colorimetry, astronomy, and laser physics.

## Interference Filters

The most common and efficient type of bandpass filter is the interference filter. The basic principles of operation of such filters are illustrated by considering the simple Fabry-Perot filter. This is made by placing a spacer of dielectric medium between two partially transmitting metal films supported on a suitable substrate. These substrates are usually glass or quartz for the visible and ultraviolet whilst in the infrared they include germanium, silicon, IRTRAN II, IV and V, sapphire, indium arsenide, indium antimonide, and arsenic trisulphide. The basic principles of operation are shown in **Figure 2**.

The optical thickness of the dielectric spacer of refractive index,  $n$ , is chosen such that it is half the desired wavelength of maximum transmission. As can be seen from **Figure 2**, the components of the transmitted beam will be in phase if the optical path length difference is an integral number of wavelengths or when eqn [1]

$$2nd \cos \theta' = k\lambda \quad [1]$$

is satisfied,  $\theta'$  is the angle in the dielectric and  $k$  is the order of the interference. The longest wavelength at which a peak occurs is given by

$$\lambda = 2nd \quad [2]$$

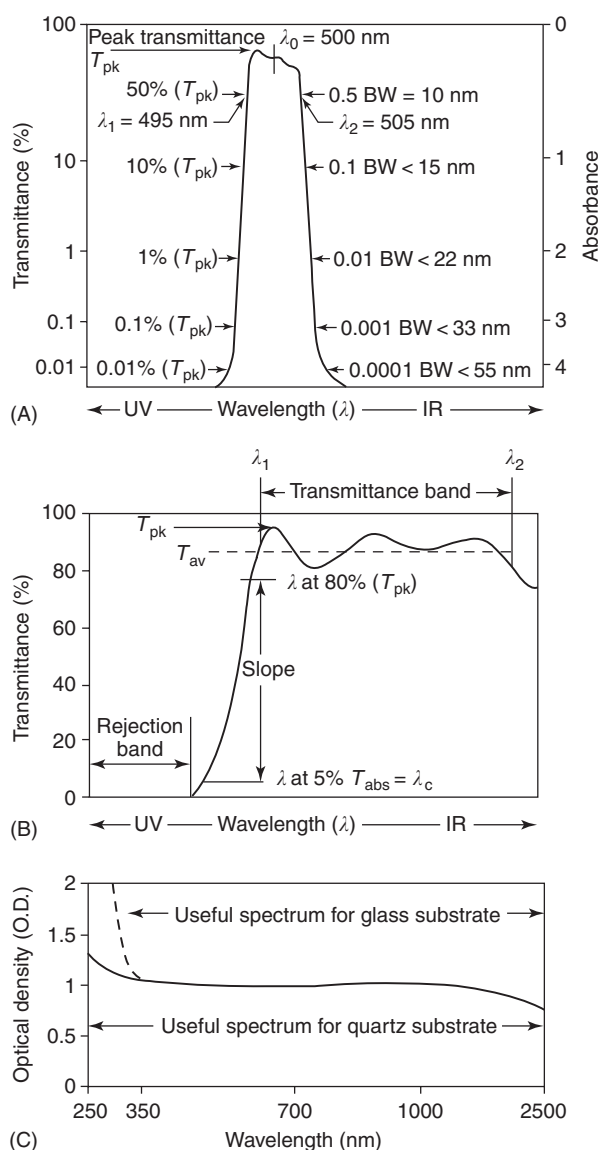

but harmonics will occur also at

$$\lambda = 2nd/k \quad [3]$$

**Table 1** Properties of the main groups of optical filters

Filter	Type	Key parameters	Use
Bandpass ( <b>Figure 1A</b> )	Interference or absorption	$T_{pk}$ -maximum transmittance of filter $\lambda_1$ and $\lambda_2$ – wavelength at 50% $T_{pk}$ at the lower and higher wavelength values Bandwidth (BW) = $\lambda_2 - \lambda_1$ Central wavelength: $\lambda_0 = \lambda_1 + \frac{\lambda_2 - \lambda_1}{2}$	Spectral isolation
Edge ( <b>Figure 1B</b> )	Interference or absorption	Transmittance band $\lambda_2 - \lambda_1$ % $T_{av}$ -average transmittance over the range $\lambda_1$ to $\lambda_2$ Cuton/cutoff wavelength at either 50% $T_{pk}$ or 5% $T_{abs}$ Slope is a measure of the sharpness of the cutoff Slope = $\frac{\lambda_{80\%T_{pk}} - \lambda_{5\%T_{abs}}}{\lambda_{5\%T_{abs}}}$	Blocking filter to remove unwanted spectral radiation
Neutral density ( <b>Figure 1C</b> )	Absorbing glass or metal coated glass or quartz	% Transmittance Spectral neutrality	Even attenuation of radiation over a selected wavelength range

**Figure 1** (A) Bandpass filter, (B) edge filter, and (C) neutral density filter. (Adapted from Corion Corporation Catalogue (1988) pp. 17, 19, 20.)

**Figure 2** Principles of Fabry-Perot interference filter. (Adapted from Grum F and Becherer RJ (1979) *Radiometry*. New York: Academic Press.)

This is the simplest type of filter and has the disadvantage that the value of  $T_{pk}$  is limited by absorption in the metallic films. More sophisticated designs are available involving only dielectric layers which give much greater transmittance but the basic principles are the same.

## Prisms

For many years, the prism formed the basis of most commercial monochromators. The spectral purity of the refracted radiation is determined by the dispersion characteristics of the prism material. The principle of operation is illustrated in Figure 3.

The collimated beam of incident radiation emerges at an angle  $\theta$  to the normal of the second surface. For each value of  $\lambda$ , the refraction is different and hence  $\theta$  is different. The rate of change of the angle  $\theta$  with wavelength  $\lambda$  is known as the angular dispersion  $d\theta/d\lambda$  and can be expressed as

$$\frac{d\theta}{d\lambda} = \frac{d\theta}{dn'} \frac{dn'}{d\lambda} \quad [4]$$

where  $d\theta/dn'$  is dependent only on the geometry of the prism and  $dn'/d\lambda$ , the dispersion, is a characteristic of the material of which the prism is made. Typical dispersion characteristics are shown in Figure 4 for some common spectroscopic materials.

From Snell's Law of refraction

$$n \sin \theta = n' \sin \theta' \quad [5]$$

In air  $n = 1$  and, at minimum deviation in the angle,  $\theta'$ , is a constant. The total deviation for both faces is  $2 \sin \theta' / \cos \theta$

Since  $\alpha = 2\theta'$

$$\frac{d\theta}{dn'} = \frac{2l \sin(\alpha/2)}{l \cos \theta} = \frac{t}{a} \quad [6]$$

**Figure 3** Principles of the minimum deviation prism. (Adapted from Grum F and Becherer RJ (1979) *Radiometry*. New York: Academic Press.)

**Figure 4** Dispersion properties of spectroscopic materials. (Adapted from Grum F and Becherer RJ (1979) *Radiometry*. New York: Academic Press.)

therefore showing that  $d\theta/dn'$  is a function only of the geometry of the prism, i.e., the ratio of the base width to the emergent beam width. This relationship leads directly to a method for calculating the resolving power of the prism.

The resolving power,  $R$ , is defined as the mean wavelength divided by the wavelength of two spectral lines which are just resolved

$$R = \frac{\lambda}{d\lambda} \quad [7]$$

Assuming a rectangular slit, then the refraction limited angular separation of two lines,  $d\theta$ , is approximately  $\lambda/a$  hence the maximum resolving power,  $R_0$  is given by

$$R_0 = t \frac{dn'}{d\lambda} \quad [8]$$

and hence the importance of the prism material.

## Gratings

A diffraction grating is a very simple optical device that operates on the principle of constructive interference. In its simplest form it consists of an optical surface upon which are cut, by means of a ruling engine, many equally spaced grooves. Gratings produced in this way are called master gratings. Replica gratings are made from the master by a technique not unlike the production of gramophone records. The line spacings have to be both small and very precise. For a UV-visible grating the line density is

**Figure 5** Principles of the diffraction grating. (Adapted from Grum F and Becherer RJ (1979) *Radiometry*. New York: Academic Press.)

of the order of 1200 lines per mm over an area of 400 mm<sup>2</sup>.

The development of gratings has taken over 100 years from the simple ruled grating to the modern holographic aspherical type. Holographic gratings are produced using a photographic process and are effectively master grating quality.

There are two fundamental types, the transmission grating and the reflection grating. The former type is not widely used in optical spectroscopy probably because the application range is limited to the absorption characteristics of the dispersion material, and will not be discussed further. Reflection gratings are subdivided into plane and concave gratings. The latter category is further subdivided into spherical and aspherical types. The following simplified discussion refers primarily to plane reflection gratings. The basic physics of reflection gratings is illustrated in Figure 5.

A collimated incident beam of radiation is diffracted by the groove in the grating surface. The angle of the diffracted beam is determined by the necessity of their being in phase (constructive interference). This will happen when the optical path difference between adjacent grooves is an integer multiple of the wavelength (cf. interference filters). This is to say when the difference between  $P_1$  and  $P_2$  (in Figure 5) is equal to an integer,  $k$ , times the wavelength  $\lambda$ .

Using basic trigonometry,

$$P_1 = d \sin i$$

and

$$P_2 = \pm d \sin \theta \quad [9]$$

where  $d$  is the groove spacing.

Note the convention to use a minus sign to indicate when  $i$  and  $\theta$  are on opposite sides of the normal and plus when on the same side. Hence

$$k\lambda = d(\sin i \pm \sin \theta) \quad [10]$$

which is the basic grating equation.

Integer  $k$  is called the order. When  $k = 0$ , i.e. zero order, then the device acts merely as a mirror and all wavelengths are superimposed on one another. When  $k \neq 0$ , eqn [10] shows that for an incident angle  $i$  then the diffracted angle  $\theta$  is dependent on wavelength  $\lambda$ . The angular dispersion is obtained by differentiation of eqn [10]; substituting for  $k$  and  $d$  yields

$$\frac{d\theta}{d\lambda} = \frac{1}{\lambda} \frac{\sin i \pm \sin \theta}{\cos \theta} \quad [11]$$

The important conclusion is that the angular dispersion of a grating depends only on the angles of incidence and diffraction. If it is arranged so that  $i = \theta$  and they are both on the same side of the normal (the Littrow mount) then

$$\frac{d\theta}{d\lambda} = \frac{2}{\lambda} \tan \theta \quad [12]$$

The theoretical resolving power of a grating monochromator is identical to that derived for a prism. Hence the smaller the intergroove distance, the greater the resolution.

## Blaze

Consider the basic diffraction grating equation for the Littrow mount, which is most commonly used in instrumentation:

$$k\lambda = d(\sin i + \sin \theta) \quad [13]$$

The light energy distribution diffracted by a grating amongst the various orders ( $k$  in eqn [13]) is illustrated in **Figure 6A**. From an optical design viewpoint, the energy should be concentrated in the first-order spectrum. This may be achieved by use of the blazing technique whereby the angle of the reflecting surfaces on the grating is changed with respect to the plane of the grating surface. The blazing is wavelength-dependent and the blazing wavelength is the wavelength at which the grating efficiency (energy throughput) is at a maximum. A detailed discussion of blazing and grating efficiencies is beyond this short overview and readers are referred to Hutley (1982).

In addition the efficiency of the grating depends upon the shape of the grooves. Basically the sharper the groove the greater is the optical efficiency. Ruled gratings have a sharper V-shaped groove and high

**Figure 6** Energy profiles of monochromatic light from a grating: (A) nonblazed; (B) blazed with improved energy profile.

**Figure 7** Effect of grating type on the efficiency: (A) ruled grating blazed at 240 nm; (B) holographic grating blazed at 260 nm; (C) sinusoidal holographic grating.

efficiency (**Figure 7A**) but poor stray light characteristics. Holographic gratings have U-shaped grooves (sinusoidal) and are much less efficient but have excellent stray light characteristics (**Figure 7C**). However, blazing of holographic gratings restores optical efficiency (**Figure 7B**) and concentrates the energy in the first-order spectrum (**Figure 6B**). Stray light is clearly an issue particularly with gratings but this topic will be dealt with in a subsequent article.

However, one of the problems with gratings is the presence of 'ghosts' between the orders due to spurious reflections. This effect is almost completely eliminated when master holographic gratings are used.

The development of gratings has been both long and complex. The main features are summarized in **Table 2**.

**Table 2** The main features of some types of gratings

Grating type	Key points	References
Simple ruled	Diamond points on speculum metal or glass	Harrison GR (1949) <i>Journal of the Optical Society of America</i> 39: 413 (historical review)
	Diamond points onto copper	Wood RJ (1944) <i>Journal of the Optical Society of America</i> 34: 509.

Echelle	Reflection grating similar properties to the reflecting echelon but easier to make. Normally used in conjunction with a prism	Harrison GR (1949) <i>Journal of the Optical Society of America</i> 39: 522.
Concave	Spherical grating in which the slit, the detector, and the radius of the grating all lie on the same circle (Rowland Circle)	Rowland HA (1883) <i>Philosophical Magazine</i> 16: 197.
Holographic	Very low stray light, high efficiency, low cost	Hayat GS and Pienchard G (1968) <i>Handbook of Diffraction Gratings. Ruled and Holographic.</i> Jobin-Yvon.

**Table 3** Choice of grating type by spectral region

Spectral region	Type	Comments
Vacuum UV	Concave grating	One reflection minimizes energy losses
UV-visible–near-IR	Plane holographic gratings up to 1400 grooves per mm, or spherical or aspherical types with diode array detection	Aspherical types correct for optical aberrations
IR and far-IR	Echelette plane gratings in Ebert-Fastie or Czerny–Turner configurations	Reflections are very high in the IR. However, elimination of high order reflections is a problem.

The application of gratings by spectral region is summarized in Table 3.

### Comparison of Gratings and Prisms

Gratings offer significant advantages over prisms in that

1. dispersion is essentially linear over their wavelength range making easier monochromator design;
2. temperature sensitivity is not nearly so great a problem as with prisms;
3. reflection gratings are available over the whole range of optical spectroscopy (plane and curved); and
4. optical systems containing gratings can be made much more compactly.

Many of the problems of the older ruled gratings, i.e. overlap of spectral orders, ghosts, high stray light

etc., have been virtually eliminated with modern holographic methods.

### Optical Configurations

The whole subject of optical mounting design occupies many volumes. The discussion herein will be limited to an overview of modern grating instruments. Of these, four designs dominate the plane grating applications namely, Littrow, Ebert–Fastie, Czerny–Turner, and Monk–Gillieson.

The object of an ideal optical configuration is that there are no optical aberrations, no stray light, and no energy loss through the system. In practice, various compromises have to be made to minimize the effect of the various variables. Within a practical optical system, five types of optical aberration are possible which give rise to image distortion, namely primary spherical aberration, coma, astigmatism (anamorphism), field curvature, and distortion.

Figure 8 Main types of optical mount.

Table 4 Comparison of strengths and weaknesses of plane grating optical mountings

Mounting type	Strengths	Weaknesses
Littrow	Simple arrangement 1 mirror 3 reflections Slit positions allow compact system and minimize astigmatism	Susceptible to coma aberration Needs paraboloid mirror Slits are close together The curvature of the slit image is wavelength dependent
Ebert-Fastie	1 mirror 3 reflections Coma compensation	Requires large mirror Needs curved slits to minimize effects of astigmatism High energy losses
Czerny-Turner	Coma compensation 2 mirrors 3 reflections	Needs curved slits to reduce effects of astigmatism High energy losses
Monk-Gilleson	Coma compensation and astigmatism correction 2 reflections 1 mirror High energy throughput	Requires large grating Subject to linear shifts in aberration

Stray light is minimized using master holographically produced gratings and energy loss is minimized by reducing the number of reflections within the optical mounting. This is particularly important in the vacuum UV. The four main optical mounts are shown in Figure 8. A comparison of strengths and weaknesses is given in Table 4.

For energy-intensive applications, concave gratings are ideal as only one reflection is required. These are based on the Rowland circle. This is illustrated in Figure 9. The optimum angle between the entrance and exit slits is  $\sim 70^\circ$ . The use of only one optical

element combines the functions of collimating, dispersing and focusing optics. The design does suffer from inherent astigmatism although in modern aspherical (ellipsoidal or paraboloidal) holographic gratings these problems can be overcome. However, they are expensive to make.

Slit Function

The slit function of a grating or prism monochromator is the image of the slit in light of the appropriate

**Figure 9** Seya-Namioka design based on the Rowland circle.

wavelength. Ideally this slit function is triangular when the monochromatic image of the entrance slit exactly fills the exit slit. The triangular slit function arises simply out of the convolution of the two identical rectangular images of the entrance and exit slits of a monochromator. If this condition is not met, i.e. different entrance and exits slit widths, then the profile is trapezoidal. The ideal situation is illustrated in **Figure 10** for equal entrance and exit slits which are larger than the diffraction limit.

See also: **Optical Spectroscopy**: Stray Light.

**Figure 10** Idealized slit function. For a nominal wavelength  $\lambda_0$  the spectral slit width is  $\lambda_2 - \lambda_1$  and  $\lambda_4 - \lambda_3$  is the effective spectral slit width (spectral bandwidth).

## Introduction

The ideal characteristics for a detector are high sensitivity, low noise, linearity of response, and uniform response with respect to wavelength.

Detection devices for optical spectroscopy fall into two distinct groups: photon detectors and thermal detectors. The fundamental difference is illustrated in an idealized way in **Figure 1**. For a photon detector, the spectral responsivity is a function of wavelength

and has a finite upper bound (long wavelength cut-off) – whereas the thermal detector's response is essentially flat.

Photon detection is generally used from the vacuum ultraviolet to the near infrared and thermal detection from the mid-infrared onwards although there is some overlap. **Figure 2** shows detector types for optical spectroscopy and detectors.

The criteria for choosing a detector are:

1. wavelength responsivity,
2. sensitivity,
3. rate of change of the optical signal to be measured (e.g., chopping frequency),
4. ruggedness, and
5. physical factors, e.g., size of beam, maximum acceptance, solid angle, uniformity of response over the detector surface etc.

**Figure 9** Seya-Namioka design based on the Rowland circle.

wavelength. Ideally this slit function is triangular when the monochromatic image of the entrance slit exactly fills the exit slit. The triangular slit function arises simply out of the convolution of the two identical rectangular images of the entrance and exit slits of a monochromator. If this condition is not met, i.e. different entrance and exits slit widths, then the profile is trapezoidal. The ideal situation is illustrated in **Figure 10** for equal entrance and exit slits which are larger than the diffraction limit.

## Introduction

The ideal characteristics for a detector are high sensitivity, low noise, linearity of response, and uniform response with respect to wavelength.

Detection devices for optical spectroscopy fall into two distinct groups: photon detectors and thermal detectors. The fundamental difference is illustrated in an idealized way in **Figure 1**. For a photon detector, the spectral responsivity is a function of wavelength

and has a finite upper bound (long wavelength cut-off) – whereas the thermal detector's response is essentially flat.

Photon detection is generally used from the vacuum ultraviolet to the near infrared and thermal detection from the mid-infrared onwards although there is some overlap. **Figure 2** shows detector types for optical spectroscopy and detectors.

The criteria for choosing a detector are:

1. wavelength responsivity,
2. sensitivity,
3. rate of change of the optical signal to be measured (e.g., chopping frequency),
4. ruggedness, and
5. physical factors, e.g., size of beam, maximum acceptance, solid angle, uniformity of response over the detector surface etc.

Photon detectors may have the first three characteristics but not the last. Thermal detectors do not enjoy high sensitivity and may be quite noisy but are generally less sensitive to wavelength.

## Photoemissive Detectors

The mode of action of this type of detector is based on the release of electrons from a photosensitive surface by absorption of photons of incident radiation. The released electrons' flow is either measured directly or amplified to provide a measure of the

**Figure 1** Idealized detector characteristics.

incident flux. If the current is measured directly then the device is known as a photocell or phototube and if amplified this is known as a photomultiplier.

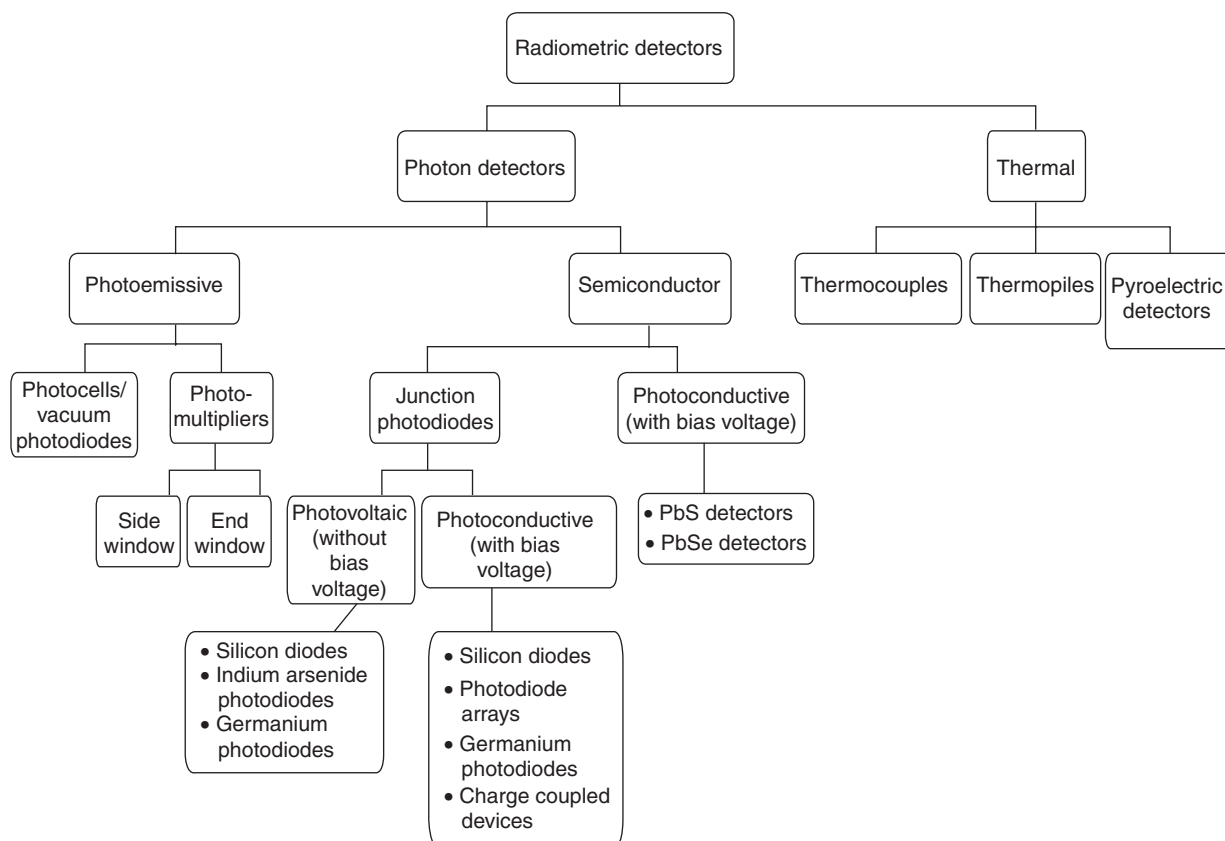

## Photocells/Vacuum Photodiodes

These are essentially simple devices consisting of a photocathode coated with an alkali metal and an anode sealed under a low-pressure argon atmosphere in a glass or quartz envelope. The coating material for the photocathode needs to be chosen for the spectral range of interest. These detectors were common in early instruments but have been largely superseded by silicon photodiodes. A schematic diagram of their construction is shown in **Figure 3**.

The quantum efficiency of these devices is somewhat low and they suffer from both short-term cathode fatigue (i.e., decrease in overall sensitivity) which is reversible after storage in the dark and irreversible cathode aging. However, they have very small dark currents of between  $10^{-9}$  and  $10^{-11}$  A.

## Photomultipliers

In effect, these are photocells with multiple amplification stages. The emitted electron from the photocathode is accelerated by a voltage drop towards an

**Figure 2** Detector types for optical spectroscopy.

electrode (the first dynode) which on impact produces a secondary electron shower. The process is continued usually up to 9 dynodes (or stages) until the anode is reached. By this stage the original photocathode current  $I_c$  has been amplified to a final current equal to  $I_c E^n$  where  $E$  is the secondary electron emission coefficient and  $n$  is the number of dynodes. The quantum efficiency of the photocathode does not usually exceed 40%.

There are two types of photomultipliers – end window and side window. The end-window design is illustrated in Figure 4.

Photomultiplier tubes (PMTs) are commercially available from 120 to 1200 nm (albeit not in one device) and have:

- a fast rise time (1–2 ns side window, 10–15 ns end window);
- excellent current amplification;
- a wide linear dynamic range (typically  $10^6$  or better); and
- a low dark current (typically 0.1–30 nA);

**Figure 3** Schematic representation of a vacuum photodiode. (Courtesy of Newport Corporation.)

**Figure 4** Schematic representation of an end-window photomultiplier tube. (Courtesy of Newport Corporation.)

but they require or exhibit:

- a high voltage stabilized d.c. power supply,
- detector cooling for photon counting applications (temperature affects the dark current),
- shielding from overexposure to light to prevent burnout,
- shielding from magnetic fields, and
- spatial sensitivity.

It is the last problem, in common with photocells, that is the greatest potential problem particularly in double beam spectrometers where image shifts can occur.

## Semiconductor Detectors

All semiconductor detectors operate on the photoconductive principle, namely the inner photoelectric effect. However, it is normal to use the term photoconductive detector for those that rely on the incident photons to change the conductivity in the bulk of the photoconductive layer. When a p–n junction is present these are called junction detectors or photodiodes. Photodiodes are generally subdivided further into photovoltaic (i.e., operating without bias voltage) and photoconductive (i.e., operating with a bias voltage). The mode of operation usually depends on the requirements for the detector electronics.

### Photoconductive Detectors

**Lead sulfide (PbS) detectors** Before the development of red enhanced PMTs, PbS photoconductive cells were widely used for detection in the red and infrared (IR) regions. They were made by depositing a sensitized microcrystalline layer of PbS on glass or quartz and attaching two electrodes before sealing *in vacuo* in glass envelope. Under dark conditions, an applied voltage produces a small current. Illumination gives increases in current proportional to the incident flux.

However, PbS detectors suffer from a number of problems including:

- variable response characteristics dependent on the manufacturing process variables;
- temperature effects on spectral responsivity, dark current, and signal-to-noise (S/N) ratio;
- the response time at room temperature is of the order of a millisecond; and
- they are very sensitive to exposure to ultraviolet (UV) or visible radiation.

A typical response curve is shown in Figure 5.

However, modern versions are much more robust and give excellent response from 800 to 3000 nm without cooling and are much more compact.

**Figure 5** Relative responses of lead sulfide and lead selenide detectors. (Courtesy of Newport Corporation.)

**Lead selenide (PbSe) detectors** These are similar in construction and mode of operation to lead sulfide detectors but have an enhanced infrared response to 4500 nm. The relative response curve shown in **Figure 5**. However, these responses are normalized in sensitivity terms. The PbSe detectors are more than 100 times less sensitive than their PbS counterparts.

### Junction Photodiodes

A schematic diagram of a junction photodiode is shown in **Figure 6**.

Incident photons absorbed in the region of the p-n junction produce hole-electron pairs. When operating in the photovoltaic mode, these hole-electron pairs migrate to opposite sides of the junction producing a voltage and consequent current flow in the detector electronics.

If, however, a reverse bias is applied across the junction, then the conductance is greatly increased thereby producing a current which is proportional to the light flux. This mode of operation is called the photoconductive mode.

**Silicon photodiodes** These are the most commonly used detectors in the region 100–1100 nm. However, UV-enhanced models extend the range into the UV to ~180 nm. They may be separated with or without bias. **Figure 7** shows some typical response characteristics.

**Indium arsenide and germanium photodiodes** Indium arsenide photodiodes are used for the near-infrared region and typically cover 1800–3600 nm. They are destroyed by bias voltages in excess of 1 V and are only separated in the photoconductive mode. They have a fast rise time (~100 ns) and give excellent

**Figure 6** Schematic representation of a junction photodiode. (Courtesy of Newport Corporation.)

**Figure 7** Spectral response for silicon photodiodes. (Courtesy of Newport Corporation.)

performance at room temperature. The spectral response region of germanium photodiodes is smaller, typically 600–1900 nm, and have longer rise times (~5 μs), but are three orders of magnitude more sensitive than indium arsenide. The output from a germanium photodiode is usually linear over a  $10^6$  intensity scale. They are best used unbiased but, unlike indium arsenide, are capable of being operated up to a 10 V bias.

**Photodiode arrays** Basically, these arrays are made up of silicon photodiodes linearly set up within an integrated circuit. The numbers in each array are typically 512 or 1024. The photocurrent from each diode causes a capacitance build-up proportional to the incident light flux, which is read by sequentially discharging the array elements via an analog-to-digital converter for data processing. These arrays have a spectral response similar to that of the silicon photodiode, i.e., 180–1100 nm. A typical sensitivity plot is shown in **Figure 8**.

The advantage of such a multichannel device is that data at many wavelengths may be collected in a single measurement cycle which, for many purposes, may be regarded as instantaneous (readout time is in the order of milliseconds). However, photodiode arrays are much less sensitive than a photomultiplier tube and if low light levels are to be observed then

cooling of the array is required. The application of diode array detectors for liquid chromatography and for UV-visible spectrophotometry has been extensive and the arrays are generally not cooled. Individual diodes are small and are typically  $25\ \mu\text{m}$  in width and  $2.5\ \text{mm}$  high.

**Charge coupled detectors** These devices are not yet commonly available in commercial instrumentation for analytical spectrophotometry although they are used in applications in inductively coupled plasma atomic emission spectrometry. However, they have found extensive application in imaging and astronomical applications. Essentially they are two-dimensional photodiode arrays which allow many spectra to be acquired in one readout. A typical array sensor is shown in Figure 9.

This has a diode pixel density of  $1024 \times 256$  giving an effective size of  $27\ \mu\text{m}$  by  $27\ \mu\text{m}$ . This device is capable of generating 74 500 spectra per second and is up to 100 times more sensitive than conventional linear diode array detectors.

## Thermal Detectors

The principle of operation of a thermal detector is that the absorption of radiation leads to one of four effects: a change in its resistance, production of a thermoelectric voltage, altered capacitance, or a rise in the temperature.

In the first category, the detectors are known as bolometers which consist of blackened thin metal strips or, if based on semiconductors, thermistors. Neither of these types is used widely nowadays in analytical spectrophotometry although bolometers have been used in infrared spectrometers.

The thermoelectric voltage effect is found in thermo couples and thermopiles. A temperature dependence of capacitance in certain materials gives rise to the pyro-electric effect.

The fourth and final effect is essentially calorimetry which is used in radiometry but does not find application in analytical spectrophotometry. However, one particular detector, the Golay detector, was formerly used in the infrared. This consisted of a chamber containing xenon gas to which was attached a mirrored membrane. Deformations in the mirrored surface caused by heat absorption were measured optically. These detectors were very expensive to make and were temperamental, and have largely been superseded.

## Thermocouples and Thermopiles

A thermocouple generates a voltage at the junction of two dissimilar metals when irradiation produces a temperature change. The metals most commonly employed are antimony and bismuth. The generation of a voltage in this way is known as the Seebeck effect. Figure 10 shows an idealized thermocouple function.

The absorption of radiation causes the temperature of the junction to rise to  $T^\circ\text{C}$  and a voltage is generated proportional to the temperature change  $\Delta T = T - T_0$ . The ratio  $\Delta V / \Delta T$  is a characteristic of the two metals and is known as the Seebeck

**Figure 10** Thermocouple, idealized diagram.

coefficient. If a number of thermocouples are placed in series (20–120 is typical), they are known as thermopiles. Thermopiles have a very wide wavelength range (200–50 000 nm), are very rugged, and no bias is required. However, they have very slow response times especially as they become larger (100–1000 ms). Commercial thermopile detectors tend to be packaged in cylindrical housings with a window. Window materials include fused silica, calcium fluoride, potassium bromide, KRS-5, Irtran, and silicon. The transmittance characteristics of this window material defines the usable spectral range. In addition, the physical robustness of the window material to humidity will limit its applicability. Spectroscopic materials are discussed in a later article.

### Pyroelectric Detectors

The pyroelectric effect is a change in surface charge (capacitance) in response to a change in temperature. Pyroelectric materials are usually crystalline and are coated with a black absorbing material. The thermal mass of these devices has to be kept small. Since it is a change in temperature which generates the current, the incident radiation must be chopped. However, the response times of pyroelectric detectors are much higher than for thermocouples or thermopiles. As with these detectors, the spectral range is largely typically 200–40 000 nm. They are used

primarily for the measurement of radiant power. These detectors have excellent stability and can usually operate between 0°C and 70°C with a relatively small temperature coefficient ( $\approx 0.2\%$  change per °C).

### Introduction

Essentially, stray light is radiant energy to which the detector is sensitive, and which should not be there. More exactly it may be described as light that lies outside the spectral bandwidth of the spectrometer. More correctly it is to be called stray radiant energy (SRE). Over the years it has caused many a spectroscopist grief by causing bias to absorbance readings, nonlinearity of response as well as false absorbance maxima.

In 1966, Edisbury was so moved as to liken the effect of stray light to a quotation from Shakespeare's

*Henry IV* (Part I iii 10) "Company, villainous company, hath been the spoil of me".

Indeed, the definition and measurement of stray light has bedevilled practical spectroscopists for more than 50 years. As far as the analytical scientist is concerned, it is instrumental stray light (ISL) that is the problem. However, optical designers are as concerned with monochromator stray light (MSL) which arises from the imperfections of optical surfaces, principally the grating, within the monochromator itself.

While, in theory, stray light is a problem throughout optical spectroscopy, most attention has been paid to the ultraviolet (UV) and visible regions and latterly to the infrared as the regions in which most problems occur.

### Instrumental Stray Light

The actual amount of instrumental stray light (ISL) is governed by the characteristics of the sample. This

coefficient. If a number of thermocouples are placed in series (20–120 is typical), they are known as thermopiles. ### Introduction

Essentially, stray light is radiant energy to which the detector is sensitive, and which should not be there. More exactly it may be described as light that lies outside the spectral bandwidth of the spectrometer. More correctly it is to be called stray radiant energy (SRE). Over the years it has caused many a spectroscopist grief by causing bias to absorbance readings, nonlinearity of response as well as false absorbance maxima.

In 1966, Edisbury was so moved as to liken the effect of stray light to a quotation from Shakespeare's

*Henry IV* (Part I iii 10) "Company, villainous company, hath been the spoil of me".

Indeed, the definition and measurement of stray light has bedevilled practical spectroscopists for more than 50 years. As far as the analytical scientist is concerned, it is instrumental stray light (ISL) that is the problem. However, optical designers are as concerned with monochromator stray light (MSL) which arises from the imperfections of optical surfaces, principally the grating, within the monochromator itself.

While, in theory, stray light is a problem throughout optical spectroscopy, most attention has been paid to the ultraviolet (UV) and visible regions and latterly to the infrared as the regions in which most problems occur.

### Instrumental Stray Light

The actual amount of instrumental stray light (ISL) is governed by the characteristics of the sample. This

can be elegantly demonstrated for direct reading spectrometers. For a given wavelength setting,  $\lambda$ , let the total detector signal be denoted by  $P_t$  and  $P_\lambda$  be that contribution to  $P_t$  made by radiation fully within the bandpass of the monochromator. An additional combination,  $P_s$ , to the total detector signal is caused by ISL outside the bandpass of the monochromator. Hence,

$$P_t = P_\lambda + P_s \quad [1]$$

If we assume a linear response for the detector, the total response in the presence of sample,  $P'_t$ , is given by

$$P'_t = P_\lambda T_\lambda + P_s T_s \quad [2]$$

where  $T_\lambda$  is the true transmittance of the sample at wavelength  $\lambda$  and  $T_s$  is the transmittance of the sample to ISL,  $s$ , at wavelength  $\lambda$ .

The apparent transmittance

$$T'_\lambda = \frac{P_\lambda T_\lambda + P_s T_s}{P_t} \quad [3]$$

but since  $P_s = sP_t$  and  $P_\lambda = (1-s)P_t$  eqn [3] becomes

$$T'_\lambda = (1-s)T_\lambda + sT_s = T_\lambda + s(T_s - T_\lambda) \quad [4]$$

Note that the sample here includes both cell and solvent. The important feature of eqn [4] is that it clearly indicates that the apparent transmittance may be greater or less than the true transmittance depending on the magnitudes of  $T_s$  and  $T_\lambda$ . One important point to be made here is that the only ISL considered is the one that causes a detector signal. This may appear pedantic but as photon detectors show a marked upper cutoff in response, so stray light of wavelengths longer than that will not matter.

The most common occurrence is that  $T_s > T_\lambda$  and hence  $T'_\lambda > T_\lambda$ , which means that the effect is an apparent low absorbance. This situation occurs primarily near source or solvent cutoffs, e.g., below 220 nm in the UV.

The effect for a variety of values of  $s$  and  $T_s = 1$  is shown in Figure 1. The limiting values of these curves are  $-\log_{10}s$ . If  $T_s < T_\lambda$ , then the opposite effect is observed namely a greater apparent absorbance. However, this is rare but may be encountered when nearing absorbance minima.

## The Measurement of Instrumental Stray Light

The concept of stray light applies to all of optical spectroscopy. However, the problems encountered are primarily in the UV portion of the spectrum. In

**Figure 1** Effect of stray light on absorbance assuming  $T_s > T_\lambda$  (eqn [4]).

reality, the problem is just as great at the upper limit of the wavelength scale but there is no easy way of measuring the effect. As far as analytical science is concerned, the practical impact of ISL is an important consideration. In concept, the amount of stray light is readily determined using a low wavelength cutoff filter.

Rewriting eqn [4] in terms of  $s$  we obtain

$$s = \frac{T'_\lambda - T_\lambda}{T_s - T_\lambda} \quad [5]$$

If the cutoff filter is effective then  $T_\lambda = 0$  and hence

$$s = \frac{T'_\lambda}{T_s} \quad [6]$$

If we assume that the filter is transparent to the stray light then

$$s = T'_\lambda = 10^{-A'} \quad [7]$$

where  $A'$  is the apparent absorbance measured at a wavelength  $\lambda$  (Figure 2). This is essentially the method defined by the ASTM. However, in practice, the apparent absorbance plateau lies beyond the scale range of most spectrophotometers. It is therefore necessary to attenuate the energy in the reference beam in order to bring it on scale.

An example is shown in Figure 3, whereby the cutoff filter used is a  $10 \text{ g l}^{-1}$  solution of potassium iodide in a 10 mm cuvette. The instrument under test was a double beam recording instrument with a

readout scale of 0–3 absorbance. Two attenuation filters (1.92 and 1.13 absorbance, respectively) were needed to observe the plateau. Hence the apparent absorbance,  $A'$ , was 5.42 and the stray light fraction calculated from eqn [7] was  $3.8 \times 10^{-6}$ .

An easier method has been proposed involving attenuation of the reference beam with the same cutoff

**Figure 2** Effect of stray light on the apparent absorbance (---) of a cutoff filter. (Reproduced with permission from Buist GJ (1981) In: Burgess C and Knowles A (eds.) *Standards in Absorption Spectrometry*, ch. VI. London: Chapman and Hall.)

**Figure 3** ASTM method. (Reproduced with permission from Mielenz KD, Weidener VR, and Burke RW (1982) *Heterochromatic stray light in UV absorption spectrometry: A new test method. Applied Optics* 21(18): 3354–3356.)

filter solution but in a 5 mm cuvette and has shown that the apparent absorbance observed under these conditions.  $A''$ , is related to the stray light ratio by

$$s \approx \frac{1}{4} 10^{-2A''} \quad [8]$$

The equivalent result for the spectrometer shown in **Figure 3** is  $4.6 \times 10^{-6}$  absorbance. The resultant trace is shown in **Figure 4**. Comparative data for 15 instruments showed good agreement between the methods (**Figure 5**).

**Figure 4** Mielenz method. (Reproduced with permission from Mielenz KD, Weidener VR, and Burke RW (1982) *Heterochromatic stray light in UV absorption spectrometry: A new test method. Applied Optics* 21(18): 3354–3356.)

**Figure 5** Comparison of the ASTM method with the Mielenz method. (Reproduced with permission from Mielenz KD, Weidener VR, and Burke RW (1982) *Heterochromatic stray light in UV absorption spectrometry: A new test method. Applied Optics* 21(18): 3354–3356.)

The slope of the line was  $1.01 \pm 0.1$  and the authors conclude that both methods give equivalent results. An alternative approach has also been developed. Experimental observations have shown that for a geometrical series of solutions, the transmittance ratio forms a minimum as the reference absorbance increases (Figure 6). The theoretical curve, for zero stray light, or true monochromatic absorbance, is curve A. Curve B shows the experimentally determined result.

These plots are determined using the following procedure:

1. For a stock solution having a monochromatic absorbance of between 4 and 5, prepare dilutions at a constant geometric ratio (1.25 is the most practical being a dilution of 20–25 ml).
2. Using the least absorbing (highest transmitting) solution first as the solution in the reference beam, measure the apparent transmittance (transmittance ratio) of the next most concentrated solution and so on.
3. Plot the transmittance ratio against the reference absorbance.

It has been shown that the stray light fraction,  $s$ , was given by

$$s = \left[ 1 + \frac{(1 - \rho)}{(\alpha - 1)} \cdot \left( \frac{\rho}{\alpha} \right)^{\frac{\alpha}{1-\alpha}} \right]^{-1} \quad [9]$$

where  $\rho$  = minimum of the transmittance ratio curve and  $\alpha$  is the geometrical concentration ratio.

For  $\alpha = 1.25$  eqn [9] simplifies to

$$s = \left[ 1 + \frac{(1 - \rho)}{0.25} \cdot \left( \frac{\rho}{1.25} \right)^{-5} \right]^{-1} \quad [10]$$

**Figure 6** Experimental observation of the transmittance ratio minimum (eqn [9]). A, theoretical curve assuming monochromatic radiation; B, experimental values. (Fleming P (1990) Transmittance ratio spectrometry as a stray radiant energy test method in spectrophotometry. *Analyst* 115: 375–378; reproduced by permission of The Royal Society of Chemistry.)

Figure 7 shows the effect of various values of  $s$  on the transmittance ratio observed as calculated by eqn [9]. Hence for any value of the transmittance ratio minimum,  $\rho$ , it is possible to calculate the corresponding value of  $s$  (Figure 8).

**Figure 7** The effect of stray light on the transmittance ratio minimum,  $\rho$ , calculated from eqn [9].

**Figure 8** Relationship between the transmittance ratio minimum,  $\rho$ , and the percentage of ISL.

It has been further shown that this approach and the one used to derive eqn (8) are theoretically equivalent.

Both these approaches suffer from the problem that values obtained are likely to underestimate the amount of stray light because of sample absorption (i.e.  $T_s < 1$ ). For conventional transmittance instruments, a method has been developed for determining the amount of stray light absorbed by the sample.

Restating eqn [4] for values of  $s \ll 1$ , it becomes

$$T'_\lambda = (1 - s)T_\lambda + s \approx T_\lambda + s \quad [11]$$

if it is assumed that  $T_s$ , the transmittance of the stray light is unity. However, if this is not the case, then a factor  $T_s^A$ , needs to be included to compensate for the attenuation of the stray light by the sample.

$$T'_\lambda = T_\lambda + sT_s^A \quad [12]$$

The contribution by the stray light to high transmittance (i.e. low concentrations of chromophore) is negligible since  $s \ll T_\lambda$  and eqn [12] becomes

$$\begin{aligned} T'_\lambda &= T_\lambda \\ \text{or} \\ \log_{10} T'_\lambda &= -A \end{aligned} \quad [13]$$

However, the contribution of stray light predominates at low transmittances (i.e. high chromophore concentrations where  $s > 50 T_\lambda$  and eqn [12] becomes

$$\begin{aligned} T'_\lambda &= sT_s^A \\ \text{or} \\ \log_{10} T'_\lambda &= \log_{10} s + A \log_{10} T_s \end{aligned} \quad [14]$$

If the observed transmittance,  $T'_\lambda$ , is plotted on semi-log axes against the monochromatic absorbance,  $A$ , then curves of the type shown in Figure 9 result;

where  $s \leq 0.02 T_\lambda$ , eqn [13] holds,

where  $T_\lambda \leq 0.02 s$ , eqn [14] holds,

where  $T_\lambda \approx s$  the 'elbow' region is observed.

The true stray light level,  $s$ , is readily available from the extrapolation of eqn [14] to  $A = 0$  and the slope gives the fraction of the stray light transmitted by the sample.

In practice, the method requires the use of a reference beam attenuation solution as in the ASTM method to allow the scale reading to be observed. The monochromatic absorbances are determined using 1 mm cuvettes and 10 mm cuvettes for the observed absorbances. Note that the term differential absorbance and transmittance ratio are equivalent.

A food dye, Orleans Blue, in aqueous solution was used to provide an arithmetic series of solutions in

the range 0–1 absorbance per mm at 630 nm. The best fit linear regression line (Figure 10) was found to be  $A_c = 0.10013c + 0.0084$  ( $\pm 0.0005$ ) $c + 0.0084$  ( $\pm 0.0026$ ). Hence monochromatic absorbances could be calculated for all solutions in 10 mm cuvettes. The measurements were repeated using 10 mm cuvettes using a 5 mm slitwidth and the results plotted (Figure 9).

To observe the second linear region, a solution having a monochromatic absorbance of 2.003 was used in the reference beam and the solutions remeasured. As the differential absorbance readings suffered fluctuation, repeated measurements were needed to estimate the mean value. The interpolation yielded a value for  $s$  of 0.0000893 ( $\pm 0.0000015$ ) and a value for  $T_s$  of 0.907 ( $\pm 0.005$ ).

## Introduction

The physical chemical and optical properties of materials involved in optical spectroscopy are of crucial importance. The quality of these materials effectively determines the quality of the data derived from spectral measurements. The majority of measurements are carried out in solution and solvent quality is a major factor in obtaining accurate data. This section will cover the optical and physical properties of

materials used to construct optical components and some consideration of solvents for spectroscopy.

## Transmitting Materials

Ideal quality considerations for transmitting materials include:

- homogeneity of refractive index;
- freedom from bubbles, inclusions, or striae;
- absence of birefringence;
- absence of fluorescence;
- wide wavelength range for high transmittance;
- very hard;
- durable to atmospheric attack particularly moisture;

**Figure 1** Typical transmittance curves for 10 mm samples of fused silica and optical glass. (Adapted from the Oriel catalogue (1993), volume 3.)

**Figure 2** Typical transmittance curves for materials commonly used in the infrared. (Adapted from the Oriel catalogue (1993), volume 2.)

- small temperature coefficients for all properties; and
- low cost and easily worked.

Not surprisingly, no material meets all these criteria.

Fused silica (UV grade) has excellent transmittance properties and is both durable and thermally stable. It finds uses as the material of choice for prisms, lenses, windows and cuvettes in the region 160–2000 nm. However, infrared grade fused silica may be used from 250 to 3500 nm. Optical crown glasses are more restricted in wavelength range from 300 to 2500 nm.

The optical transmittance properties of materials used in the ultraviolet through to the infrared are shown in **Figure 1**. A similar transmittance plot for optical materials used in the infrared is shown in **Figure 2**. However, optical properties are only one of the factors to be considered, particularly in the

**Figure 3** Reflectance characteristics of optical materials used for mirrors. (Adapted from the Oriel catalogue (1993), volume 2.)

Calcium fluoride	–	3.18	1423	1.4	Small	No	– 9	200–8 000 21 000–38 000	Hard material slowly attacked by moisture
KRS-5				2.37	Small	No	–	600–35 000	Thallium bromiodide. Very wide transmission but soft material
Germanium	–	5.35	937	4	None	No	–	2000–16 000	Very durable but nontransmitting above 150°C
Silicon	–	2.33	1410	3.42	None	No	–	1300–11 000	Similar to germanium; nontransmitting above 350°C
IR fused silica	530	2.209	1585	1.43	None	No	10	2600–4 000	Durable material unaffected by water
Zinc selenide	120	5.27	1100	2.41	None	No	61 at 10 500 nm	550–16 000	Very expensive but used extensively in laser applications
Sapphire	1370	3.97	2040	1.70	None	Slightly	–14	150–5 000	Durable material unaffected by water
Zinc sulfide (IRTRAN 2)	160	4.09	1020	2.23	Very small	No	39 at 33 900 nm	400–12 000	Very soft material but better visible- region properties than zinc selenide
NaCl	18	2.16	1074	1.51	Small	No	$-3 \times 10^{-5}$	250–16 000	Similar to potassium bromide but less susceptible to water and extends to the UV

infrared. The ability to work the material and its durability are also key factors. Some of the factors are summarized for commonly used materials in Table 1. The materials are used in the construction of lenses, cuvettes, prisms and sample cell windows.

## Reflecting Materials

Mirrors were for many years primarily aluminum-coated glass. Recently, however, coatings of magnesium fluoride or silica onto aluminum have increased their durability and lasting reflectance properties. All reflectors deteriorate with time, atmospheric attack and radiation damage.

Very specialized coatings, e.g., rhodium, are very expensive but have excellent reflectance characteristics when optimized for the ultraviolet.

Above 2000 nm most of the materials show high reflectance. Figures 3A and 3B shows the reflectance characteristics of some commonly used materials.

Gold has such excellent properties above 800 nm that it is the material of choice for near-infrared and mid-infrared integrating spheres.

## Solvents

The quality of the spectroscopic solvent is sometimes overlooked. The analytical scientist needs to consider:

- the transmittance properties of the solvent;
- the transmittance properties of the sample of the solvent being used;
- the chemical stability of the solvent;
- the temperature coefficient at expansion and the volatility of the solvent; and
- health and safety aspects associated with its use.

As a rule of thumb, do not operate using a solvent with less than 50% transmittance at the analytical

**Table 2** Lower wavelength values for 50% transmittance of common spectroscopic grade solvents

<i>Solvent</i>	<i>λ at 50% T</i>
Hexafluoropropan-2-ol	< 190 <sup>a</sup>
Hexane	208
Heptane	209
Isooctane	210
Isopropanol	218
Ethanol	218
Methanol	210
Cyclohexane	220 <sup>b</sup>
Diethyl ether	232
Dioxan	235
Dichloromethane	237
Chloroform	250
Tetrahydrofuran	250
Dimethylformamide	273
Dimethylsulphoxide	282
Benzene	283
Pyridine	305
Acetone	350
Water	190 <sup>c</sup>

<sup>a</sup>Hexafluoropropan-2-ol has 90% transmittance at 200 nm.

<sup>b</sup>The removal of oxygen by nitrogen purging of hydrocarbon solvents decreases the transmittance markedly, e.g., for cyclohexane  $\lambda$  at 50%  $T$  decreases to 205 nm after purging.

<sup>c</sup>Doubly distilled water (glass apparatus) may be used down to 180 nm if purged of dissolved oxygen. However, contact with plastics and polyethylene dramatically reduces its transmittance below 200 nm. Perkampus HH (1992) *UV Atlas of Organic Compounds*, 2nd edn. Weinheim: VCH.

wavelength unless forced and then only if it can be ascertained that stray light is not a problem.

All solvents should be checked before use even if spectroscopic grade solvents are chosen. The storage of spectroscopic solvents needs particular care. Store in glass, in amber bottles, preferably under nitrogen for work of the highest quality.

Table 2 contains information relating to commonly used spectroscopic solvents.

## Refractometry and Reflectometry

### Refractometry

Refractometry is an analytical technique that characterizes structure and composition of materials by the velocity of light transmitted through them. The result of the measurement is usually expressed as the ratio of the velocity of light through a vacuum ( $c$ ) to that of the sample ( $v$ ), and is referred to as the refractive index:

$$n = \frac{c}{v} \quad [1]$$

Table 1 shows the refractive indices for several materials. The variation of refractive index as a function of electromagnetic radiation wavelength (dispersion spectrum) provides simultaneous information about the polarizability and absorption properties of the sample. The rapid development of modern optical and imaging technologies such as lasers and photodiode arrays creates opportunities for application of refractometry to small analytical systems and multi-dimensional monitoring.

### Theory

The decrease of light velocity in the sample compared to vacuum is caused by the interaction of electromagnetic radiation with electron clouds present in the specimen and therefore corresponds to electron density and their state of binding. Light velocity and refractive index vary as a function of wavelength and generally increase with an increase in

frequency for nonabsorbing materials. Figure 1 shows the variation of refractive index for fused quartz. For absorbing species, the situation is more complex since significant variations in the refractive index occur near the absorption bands, as shown in Figure 2. This phenomenon is produced as the result of major changes in the charge configuration associated with electronic transitions. These changes will induce polarizability and therefore increase the refractivity of the absorbing species. With decreasing frequency near the absorption band the refractive

**Figure 1** The refractive index of fused quartz as a function of light wavelength.

**Figure 2** (A) Refractive index,  $n$ , and (B) dielectric constant,  $\epsilon = (n - ik)^2$ , related to absorption coefficient,  $k$ , around a resonance frequency,  $\omega_r$ , for a Lorentzian oscillator. Half-width of the absorption curve is  $Y_r$ .

**Table 1** Selected refractive indices for  $\lambda = 589$  nm (yellow sodium light), 1 atm, and 20°

Air	1.000293

Sapphire	1.77
Diamond	2.42

index first falls to a minimum, then increases through  $n_0$  at the resonance frequency to a maximum, and finally levels off to the initial value  $n_0$  (see **Figure 2A**). A dramatic decrease of refractive index near the absorption band is referred to as ‘anomalous dispersion’. Variation of the refractive index, as a function of electromagnetic wavelength, is called the dispersion spectrum. At low frequencies (at the radio and microwave ranges) the presence of ions and polar molecules in the sample affects the electromagnetic wave propagation through the media. However, at high frequencies, characteristic of visible light, only the polarizability of low mass valence electrons determines the refractive index of the sample. Near the resonance frequency another effect associated with loss of light intensity will occur due to absorption (see **Figure 2B**). This is expressed as an imaginary part of the dispersion spectra and corresponds to the absorption curve.

The degree to which an electromagnetic wave is slowed down upon entering a given medium depends upon the characteristics of the electronic environment it encounters. This is a function of the individual molecular electron clouds, as well as the number of molecules per unit volume,  $N$  (particle density). If the medium contains  $N$  molecules per unit volume, the magnitude of the charge distortion in the molecules by the electromagnetic field of the radiation is limited by their polarizability,  $\alpha$ , and the dielectric constant,  $\varepsilon$ , of the medium. The relationship between these parameters is expressed in the Clausius–Mosotti equation:

$$\frac{\varepsilon - 1}{\varepsilon + 2} = \frac{4}{3} \pi N \alpha \quad [2]$$

Moreover, according to Maxwell’s theory of the electromagnetic field:

$$\varepsilon = n_\infty^2 \quad [3]$$

where  $n_\infty$  is the refractive index corresponding to an infinitely long wavelength. Since  $N$  is proportional to the density,  $d$ , eqn [2] can be rewritten to yield the Lorentz–Lorenz expression for specific refraction,  $r$ :

$$r = \frac{n_\infty^2 - 1}{n_\infty^2 + 2} \frac{1}{d} \quad [4]$$

Specific refraction is a measure of the polarizability of the system involved, corrected for the variation in the number of molecules per unit volume. It refers to the volume of the electron clouds themselves, and does not include the empty spaces in the medium. Therefore, it is a measure of the electronic properties of the molecules. If the electronic

structures of the molecules are not changed due to the intermolecular forces, the specific refraction is independent of temperature, pressure, or state of aggregation.

Based on the above discussion, it is expected that the refractive index of a sample varies with temperature, pressure, and its composition. The decrease in refractive index with increasing temperature and decreasing pressure is primarily the result of the expansion of the media volume and decrease in density, causing the light beam to encounter fewer molecules per unit distance. These effects can be calculated by considering thermal expansion or compressibility parameters.

The refractive index for multicomponent mixtures is not an additive function. In the first approximation, the change in the refractive index of the medium,  $\Delta n$ , can be calculated by assuming that the densities of the medium and the solute are similar:

$$\Delta n = \frac{M_s}{m_M} (n_s - n_M) \Delta C \quad [5]$$

where  $M_s$  is the molecular weight of a given solute,  $C$  the solute concentration,  $m_M$  the mass of 1 l of medium with solute, while  $n_s$  and  $n_M$  are refractive indices of solute and medium, respectively. A more precise relationship can be derived from the Clausius–Mosotti relation (eqn [2]), which leads to the following relationship:

$$\Delta n = \frac{M_s C_s}{m_M K_M} (F_s - F_M) \quad [6]$$

where

$$F_s = (n_s^2 - 1)(n_s^2 + 2)$$

$$F_M = (n_M^2 - 1)(n_M^2 + 2)$$

$$K_M = 6n_M / (n_M^2 + 2)^2$$

## Principles of Refractometric Instrumentation

Differences in refractive indices among naturally occurring materials often result in refraction, that is, deflection of the light path. This optical phenomenon is frequently used to measure the refractive index or its changes. **Figure 3** illustrates the refraction of the light at the boundary between two materials with different refractive indices ( $n_1 > n_2$ ). The refraction of the light at the boundary can be explained by considering the light as a wave as shown in **Figure 3B**. As the wave crosses the interface it speeds up when it encounters the lower refractive index, resulting in a change in the direction of propagation. The

relationship between the angle of incidence  $\theta_1$  and the angle of propagation  $\theta_2$  can be derived from Figure 3B and is defined by Snell's Law:

$$n_1 \sin \theta_1 = n_2 \sin \theta_2 \quad [7]$$

A portion of the light is also reflected from the surface (Figure 3A). The intensity of reflected light is dependent on its polarization and is defined by Fresnel's law of reflection. It is a function of  $n = n_2/n_1$

and angle of incidence  $\theta$ :

$$I_2(\parallel) = I \left( \frac{-n^2 \cos \theta + \sqrt{n^2 - \sin^2 \theta}}{n^2 \cos \theta + \sqrt{n^2 - \sin^2 \theta}} \right)^2 \quad [8]$$

$$I_2(\perp) = I \left( \frac{\cos \theta - \sqrt{n^2 - \sin^2 \theta}}{n^2 \cos \theta + \sqrt{n^2 - \sin^2 \theta}} \right)^2 \quad [9]$$

where the  $I_2(\parallel)$  is the intensity of the light parallel to the surface and  $I_2(\perp)$  the intensity of reflected light polarized perpendicular to the surface.

For  $\sin \theta > n_2/n_1$ , total reflection of the light occurs at the boundary. This phenomenon is the principle of the popular Abbé refractometer (see Figure 4). A small amount of liquid sample is introduced between prisms  $P_1$  and  $P_2$ . Usually, the prisms are kept at constant temperature using thermostated water. The light beam illuminates the prisms from below with the help of the mirror  $M$ . The prisms  $P_1$  and  $P_2$  are attached to a rotatable arm,  $A$ , which carries a marker and magnifier to facilitate accurate readings,

**Figure 3** Graphic illustration of Snell's law of refraction. (A) Refracted and reflected light beam at the refractive index boundary for  $n_1 > n_2$ . (B) The refraction of the plane wave. Reflected wave is not shown.

**Figure 4** Schematic view of an Abbé refractometer. A, rotatable arm; S, sector scale;  $P_1$ , auxiliary prism;  $P_2$ , refracting prism; T, telescope; L, telescope lenses; E, eyepiece; X, magnifier; M, illumination mirror.

using a fixed scale S. The reading of the scale is a measure of the angle between normal to the surface and the telescope axis. The telescope, T, is equipped with cross hairs, which are aligned with the observed critical boundary. The resulting light emergence angle,  $r_c$ , corresponds to the characteristic of the sample and the prism. The refractive index of the sample,  $n$ , can be calculated using the following equation:

$$n = \sin r_c \cos \beta + \sin \beta (n_p^2 - \sin^2 r_c)^{1/2} \quad [10]$$

where  $\beta$  is the prism angle and  $n_p$  its refractive index. Typically, the instrument is designed to use white light, but readings can be made for a sodium line (589.3 nm) by applying optical filters based on Amici prisms. The standard Abbé refractometer allows the estimation of the refractive index to  $\pm 0.0001$ . There are several other types of refractometers based upon various optical phenomena such as interferometry, light diffraction, Snell's law of refraction, and Fresnel's law of reflection.

### Schlieren Optics

The refraction of light is also caused by a non-homogeneous refractive index within the sample. For example, the nonuniform distribution of the analyte in a medium will generate a corresponding refractive index gradient:  $dn/dx = (dn/dC)(dC/dx)$ . The light propagated through the medium with such a gradient will produce a 'streak' ('*schliere*' in German; '*mirage*' in French). Such an effect can be easily observed when dissolving sugar in water. A similar effect can be produced by temperature gradients, for example, above a hot surface ( $dn/dx = (dn/dT)(dT/dx)$ , where  $T$  is temperature), which is a principle of indirect absorption methods based on photothermal deflection techniques including thermal lens spectrometry. The physical principle of this phenomenon is illustrated in **Figure 5**. The wavefront, I, of the light beam encounters the refractive index gradient field at time  $t$ . The different sections of this wavefront experience different refractive indices. Therefore, various parts of the probe beam will propagate through the gradient in the medium with different velocities since the velocity is inversely proportional to the refractive index (eqn [1]). After a time increment,  $dt$ , the parts of the beam that experience a lower refractive index will have propagated further than those in other regions, resulting in a tilted wavefront II, formed at time  $t + dt$  with respect to wavefront I. The net effect is a deflection of the light beam toward higher refractive indices since light, similar to other types of waves, propagates perpendicular to its wavefront. The quantitative relationship

**Figure 5** Principle of Schlieren optics. (A) Tilting of the light wavefront propagating through the medium with a nonuniform refractive index. (B) Refraction of the light beam passing through the detector cell with the concentration gradient produced by solute.

between the deflection angle,  $\theta$ , and the detector cell dimension,  $L$ , assuming a uniform refractive index gradient,  $dn/dx$ , normal to the probe beam direction (**Figure 5B**), can be derived using Fermat's principle; it states that the light path through a medium is such that the time necessary for its traversal is a minimum, which results in

$$\tan \theta = \sinh \frac{L}{n} \frac{dn}{dx} \quad [11]$$

where  $n$  is the refractive index of the medium. For most practical analytical cases, where  $L$  and  $\theta$  are small, we can approximate  $\theta$  by

$$\theta = \frac{L}{n} \frac{dn}{dx} \quad [12]$$

Many different optical systems have been developed to investigate refractive index inhomogeneities using the light deflection phenomenon described above. These methods are usually referred to as Schlieren

**Figure 6** Example of Toepler–Schlieren optical system. L1, collimated lens; L2, Schlieren head; L3, objective lens; K1, first knife edge (aperture); K2, second knife edge.

optical techniques. In these methods, the light beam is passed through an object with an inhomogeneous refractive index. After some optical signal processing, the beam is recorded on a photographic plate or more recently on photodiode array sensors. The change in the intensity distribution across the probe beam reflects the refractive index gradient fields present in the object. An example of such a system is shown in **Figure 6**. In this arrangement, the angle of deflection is transformed into a light intensity variation in the image of the object, on the photographic plate or screen. The region of high gradients is indicated by darker or lighter regions in the image. In the Toepler–Schlieren (**Figure 6**) system, an image of the light source is produced at ‘S’ and an image of the object is produced at point ‘O’. The knife edge K2 intercepts the image of the source, sharpened by aperture K1. The deflection of the beam produced by the upward directed gradient will cause the light to miss the K2 edge. If no gradient is present, or its orientation is downwards, then the appropriate light will be blocked. Therefore, the net effect will be that the lighter areas in the image of the object indicate regions in which gradients are directed upwards. The rest of the image will be dark.

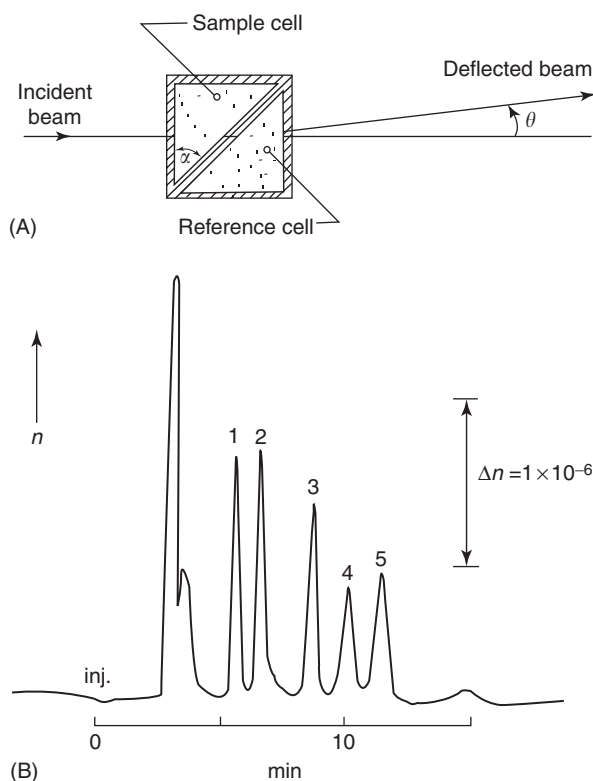

The magnitude and direction of the gradient can be studied by moving the knife edge deeper into the image of the light source. Starting from the non-intercepting position, the areas of the object with highest gradients directed downwards will be darkened first, followed by areas with no gradient, and then finally areas with gradients directed upwards. Scanning the knife edge allows only for the analysis of the gradients directed perpendicular to the edge. Simultaneous analysis in both directions can be accomplished by using a centrosymmetric aperture made, for example, of shaded or colored centrosymmetric rings. The magnitude of the deflection is indicated by the darkness or the color of the image. In addition, the direction of the deflection can be determined using an aperture made up of colored regions.

The velocity of light through the sample is not identical in all directions in anisotropic materials, where the polarizability of the electron clouds varies in relation to optical axis. Similarly, propagation of circularly polarized light can differ depending on its orientation if the sample contains optically active material. This effect can be monitored by measuring the rotation angle of the linearly polarized light. This phenomenon is the principle of the analytical technique called polarimetry.

## Applications

In principle, absolute values of the refractive index can be used to identify chemical species in the same fashion as boiling and melting points, and the density of light absorption properties. Specific refraction and dispersion spectra are used to characterize the chemical structure of analytes. However, it is very difficult to apply refractometry for this purpose because of small differences in refractive index between substances, and relatively large dependence of the index with temperature, dissolved gas, and impurities. This method has been used more successfully in combination with microscopy to differentiate between components of inhomogeneous solid samples.

A more important application of this method is to quantify the composition of well-defined binary systems in which pure components differ appreciably in refractive index and an approximately linear relationship exists between  $n$  and the concentration of analyte. An example is the determination of protein or sugar content in aqueous solutions. One of the most important applications of refractometry is the measurement of refractive index in flowing liquids, particularly in high-resolution liquid chromatography. The refractive index measurement is done in a difference mode as shown in **Figure 7A** for the beam deflection type of the detector. In a typical design, two adjacent triangular cross-section cells are used (**Figure 7A**). When the refractive index of the effluent in one cell is the same as in the reference cell, which contains a mobile phase, the probing light is not deflected. As the composition of the liquid changes in the first cell, because of elution of sample components, the refractive index of the mixture changes, resulting in light deflection. The major advantage of the refractive index detector over other methods is its universal response. Usually, the solute differs from the eluting solvent in refractive index by  $\sim 0.1$  units. This enables the detection of analytes at only semi-trace ( $\text{mg l}^{-1}$ ) levels. However, in some cases this is the most sensitive detector available. For example, in the analysis of sugars, absorption or fluorescence

**Figure 7** Refractive index detection in liquid chromatography. (A) Dual-triangular section flow cell for detector based on Snell's law. detection cannot be used effectively. **Figure 7B** shows an example of the separation and detection of a sugar mixture.

The refractive index detector also plays an important role in the characterization of polymeric mixtures and natural materials such as crude oils after exclusion chromatographic analysis. The interesting feature of this method is its ability to quantify multicomponent samples without standards. As shown in eqn [5], the magnitude of the signal for the two unknown quantities is determined by their concentrations and refractive indices. However, in the case where the same sample is eluted by different solvents, characterized by different refractive indices but having identical elution characteristics to the first one, different peak magnitudes will be observed. The two signals give rise to two independent equations, which can be solved to determine both the concentration and the refractive index of the analyte. **Figure 8** illustrates the separation and quantification of components present in two types of crude oil.

### Trends in the Use of Refractometry

**Miniaturization** Application of lasers as light sources resulted in a reduction in the size of refractive index detectors and made them compatible with in-line monitoring systems that are needed in capillary separation technology. The refractive index of minute amounts of solution may be determined by the measurement of the diffraction phenomenon produced in the interaction between the laser beam and a fluid-filled capillary. The laser beam passing through an off-center capillary produces a fan of scattered light in the plane perpendicular to the tube axis. The position of a single line corresponds to the refractive index of the fluid within the tube

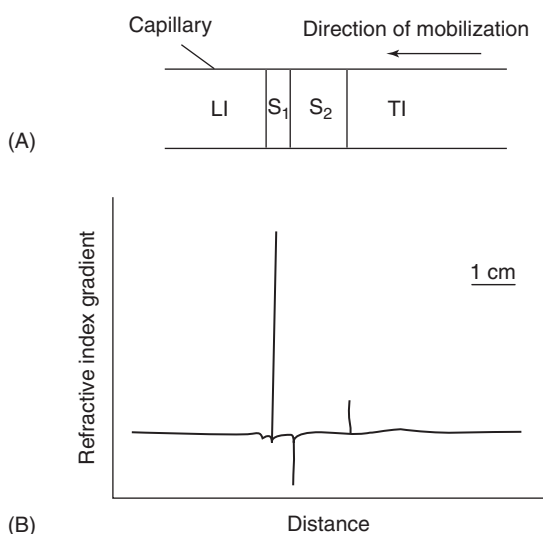

**Figure 9** Refraction of a light ray by a fluid-filled tube. (Reprinted with permission from Bornhop DJ and Dovichi NJ (1986) *Analytical Chemistry* 58: 504–505; © American Chemical Society.)

(Figure 9). With micrometer diameter tubes, such a refractive index detector can probe volumes approaching a few picoliters and result in femtogram detection limits. This feature makes this detection scheme very useful in small channel separation techniques, such as capillary and chip technology.

**Concentration gradient detection** In many modern analytical methods, such as electrochemical and high efficiency separation techniques, high concentration gradients are generated, which produce a highly inhomogeneous refractive index field in the system and can be effectively detected by the Schlieren optics methods. These investigations have traditionally been used only for qualitative observations. However, the development of new optical technology such as lasers and imaging systems facilitate quantitative applications.

**Figure 10** illustrates the application of a Schlieren optics detector for capillary isotachopheresis (cITF). In cITF, ionic analytes are separated into pure distinct zones that are stacked according to their mobility. The zones then migrate with constant velocity toward the common electrode (Figure 10A). In this technique, the sample is introduced between leading and tailing electrolytes that have higher and lower mobilities, respectively, than the components of the analytical mixture. The boundary between the zones formed in this technique is very narrow due to the sharpening effect. Also, the zones contain high concentrations of analytes because of the concentration effect. These properties of the method ensure the formation of high concentration gradients at the zone boundaries that can be readily detected by the gradient methods (Figure 10B). The high spatial resolution and universal response of the laser-based Schlieren optics method (see Figure 5B) allows sensitive and quantitative detection of all zones produced during electrophoretic separation.

Another capillary electrophoretic method that possesses both concentrating and focusing properties is capillary isoelectric focusing. In this technique, a pH gradient is formed inside the capillary using synthetic

**Figure 10** (A) Capillary isotachopheretic separation and (B) concentration gradient detection of two cations. Sample: S<sub>1</sub>, hexadecylammonium and S<sub>2</sub>, triphenylphosphonium ions. Leading ion (LI) is ammonium ion and tailing ion (TI) is tetraoctylammonium ion. carrier ampholytes. The ampholytic samples, such as proteins, are concentrated at their isoelectric points inside the capillaries. The analytes are then mobilized toward one end of the capillary for detection. The analysis time can be substantially reduced (from ~30 to 2 min) by eliminating the mobilization step when applying imaging methods of detection. In the Schlieren shadowgraph system shown in Figure 11, the laser beam is expanded and focused into the separation capillary using a cylindrical lens in between (Figure 11A). The diode array detects changes in the light intensity distribution caused by the presence of the analyte bands. For the optical alignment shown in Figure 11A, in theoretical treatment, the probe beam can be decomposed into a bundle of infinitesimal light filaments. The individual light filaments are refracted and deflected from their original path upon encountering a refractive index gradient. This gradient is produced by the concentration gradients generated inside the capillary by concentrated analytes. As suggested in Figure 11B, the relative changes of the probe beam intensity on the detector plane are proportional to the second derivative of the refractive index inside the capillary. Figures 11C and 11D show an application of this method to separation and quantification of protein samples and the investigation of interaction between biological species. Schlieren imaging is the best possible choice for *in vitro* monitoring of formation and dissociation rates of biological complexes since it detects all

**Figure 11** Concentration gradient imaging detection in capillary isoelectric focusing. (A) Experimental arrangement and (B) principle of the imaging system. species present in the capillary and does not disrupt the system by introducing energy through absorption processes. Toepler–Schlieren optical arrangement (see Figure 6) can be used in place of the shadowgraph system (Figure 11) to enhance sensitivity of the imaging detection.

## Reflectometry and Differential Reflectometry

Refractometry and reflectometry both use visible (or near-visible) light to investigate a given material. Refractometry is generally utilized to study transparent materials such as glasses, transparent polymers, or a number of chemical species described in the above sections. On the other hand, dense materials such as metals, alloys, semiconductors, etc., are generally studied in reflection because of the short penetration depth of light into these materials. The ratio between the reflected intensity  $I_R$  and the impinging intensity  $I_0$  of the light serves as a definition for the reflectivity (see Figure 3A):

$$R = \frac{I_R}{I_0} \quad [13]$$

The spectral reflectivity of dense materials is generally a complicated function of the index of refraction (see eqn [1]) and a parameter  $k$  that describes the amount of damping of the light within the material. (The damping constant  $k$  is often neglected in glasses, etc., because of its extremely small value for these materials.)

As occurs in the refraction ‘spectrum’ shown in Figure 1, the reflectivity spectrum is often relatively featureless. Thus, a first derivative technique is generally applied which enhances the ‘structure’ in a conventional reflection spectrum. This enhancement technique, which allows one to emphasize small pieces of information in a relatively featureless reflection spectrum, is called differential reflection spectrometry. Refractometry and differential reflection spectrometry complement each other for their respective fields of applications.

## Principles of Reflectometric Instrumentation

The differential reflection spectrometer (also called the differential reflectometer) measures the normalized difference between the reflectivities of two specimens (or two slightly different parts of a specimen) as a function of photon energy. Unpolarized, monochromatic light (having the possibility to vary the wavelength continuously) is alternately deflected to one or the other sample by means of a vibrating

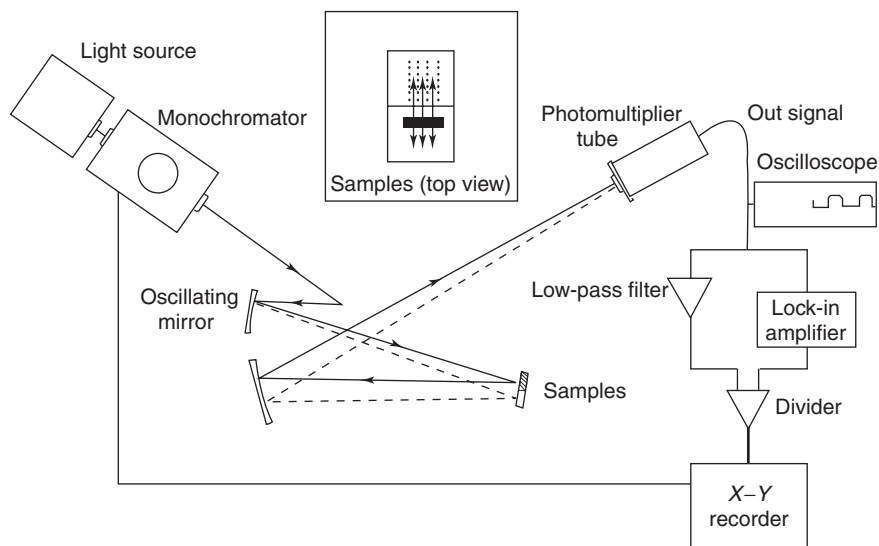

mirror that oscillates at a convenient frequency such as 50 or 60 Hz (Figure 12). The cross-section of the light beam is rectangular and is parallel to the boundary that separates the two samples. This beam sweeps over the two specimens perpendicular to the boundary and at near normal incidence to the surface (see the insert of Figure 12). The total area scanned is generally  $2 \times 4 \text{ mm}^2$ , but can be varied in size by regulating the voltage to the vibrator coils driving the mirrors. The light that is reflected by the two samples eventually reaches a light-sensitive device. The signal thus obtained is electronically processed to yield  $\Delta R/\bar{R}$ , where  $\Delta R = R_1 - R_2$ , is the difference in reflectivity between the two specimens and  $\bar{R} = (R_1 + R_2)/2$  is the average reflectivity. Measuring  $R_1$  and  $R_2$  at the same time and forming the ratio between  $\Delta R$  and  $\bar{R}$  eliminates possible influences from fluctuations of the line voltage. It also eradicates intensity variations in the spectral output of the light source, the spectral sensitivity of the detector, and the spectral reflectivities of the mirrors. Further, owing to the difference-forming technique, all disturbances of the surface (such as roughness, oxidation, contamination) are eliminated as long as they are common to both sample parts.

The output signal from the divider circuit of the differential reflectometer is fed to the Y-axis of an X-Y recorder (Figure 12). A potentiometer attached to the scanning gear of the monochromator delivers a d.c. voltage proportional to the wavelength that is fed to the X-axis of the X-Y recorder. In this way, a differential reflectogram, i.e., a continuous plot of  $\Delta R/\bar{R}$  versus wavelength (or photon energy), is

generated automatically without necessitating individual measurement and computational stops at narrowly spaced wavelength increments, as required by spectroscopic ellipsometry. A scan between 200 and 800 nm (1.6–6.0 eV) requires from 1 to 3 min, depending on the scanning speed selected. The sensitivity in observing the normalized difference in reflectivity is better than one-hundredth of a percent.

### Applications

The differential reflectometer is successfully used in a number of research fields such as the study of the electronic structure of alloys, order-disorder transformations, investigations of surface films, corrosion, or the effects of ion implantation in semiconducting materials. The differential reflectometer is also helpful when the nature and the thickness of one or several active layers in an electronic device need to be quickly and nondestructively determined. The peaks in the ultraviolet (UV) region of differential reflectograms indicate whether or not a change in the electronic structure of the top layer ( $> 1 \text{ nm}$ ) of the host material (caused by doping, lattice damage, chemical reactions, etc.) has taken place. Further, the UV peaks provide information concerning whether or not a disturbed layer is submerged below an essentially unperturbed area. On the other hand, the interference peaks in the infrared region yield the thickness of a specific layer. Further, differential reflectometry is well suited for a quick and nondestructive check of semiconductor wafers, stemming from different vendors or lots, and for monitoring

**Figure 12** Schematic diagram of the differential reflection spectrometer. For clarity, the angles of the incident and reflected light beams on the sample are shown larger than they are in reality.

**Figure 13** Differential reflectograms for various copper-zinc alloys. The information is obtained from a surface layer of approximately 100 nm thickness. The parameter on the curves is the average zinc concentration of the two alloys given in at.%.

possible deviations from a reference wafer that has been shown to have required properties.

The usefulness of differential reflection measurements will be illustrated here on a characteristic sample. Copper is a reddish metal which changes its color toward yellow when zinc is added to it (to form brass). This change in color, which has its origin in an increase in the average number of electrons when bivalent zinc is added to monovalent copper, can be followed in a series of differential reflectograms.

Figure 13 depicts the normalized difference in reflectivity between various copper-zinc alloys as a function of the wavelength of the light (or the photon energy). A number of peaks designated A–D can be observed. The peak marked ‘A’, which is situated in the red part of the spectrum, relates to the color of this alloy. It is observed in Figure 13 that with increasing zinc content peak A moves to higher photon energies, that is, from red to yellow. In other words, differential reflectometry can provide nondestructively and rapidly a qualitative account of the chemical composition of solid materials.

### Origin and Nature

Ozone ( $O_3$ ) is a colorless gas at ambient temperature and pressure and has a characteristic odor even at very low concentrations. It has a strong oxidizing ability that is hazardous to plants and animals, and is unstable especially at higher concentrations. Electric discharge in oxygen (or air) and irradiation of oxygen (air) with short-wavelength ultraviolet (UV) rays produce ozone.

Ozone plays important roles in atmospheric chemistry and physics. Up to  $5 \times 10^{12}$  molecules  $cm^{-3}$  or 4–5 ppmv ( $10^{-6}$  mixing ratio by volume) of ozone is found in the stratosphere where the solar radiation intensity of shorter wavelengths is high. Ozone in the stratosphere has made it possible for animals to live on land by preventing harmful 200–300 nm UV radiation from reaching the Earth's surface. The absorption of UV radiation by ozone, however, heats the air, disturbing air convection and creating a layered structure in the stratosphere. As some useful and stable chemicals like chlorofluorocarbons (Freons) and other substances were found to decompose in the stratospheric environment and to destroy the

ozone layer by chain reactions, ozone levels in the stratosphere have been monitored with great concern.

In the lower troposphere, photochemical reactions of air pollutants (hydrocarbons and nitrogen oxides) produce ozone as well as other atmospheric oxidants such as hydrogen peroxide ( $H_2O_2$ ), organic peroxides, and peroxyacyl nitrates that result in what is called photochemical smog. Daytime ozone concentrations often exceed 0.1 ppmv in polluted air. Ozone and other oxidants promote oxidation of sulfur dioxide ( $SO_2$ ) and nitrogen oxides into sulfuric and nitric acids, respectively, bringing about the occurrence of acid rain. In addition, ozone has strong absorption bands in the infrared region near  $9.6 \mu m$ , and hence is one of the so-called greenhouse gases. Monitoring of ozone concentration is thus indispensable for protection of both the local and global environment.

Ozone is also emitted from germicide lamps, copy machines, printers, welding, and other industrial processes. The working environment criteria for ozone are set at 0.05–0.1 ppmv in most countries. Monitoring of ozone is therefore important from the viewpoint of workplace health and hygiene.

Ozone is being used in the field of water treatment, disinfection, decolorization, deodorization, organic synthesis, materials testing, dry etching and cleaning processes in semiconductor industries, and other industrial areas. The advantages of using ozone over other chemicals are: its strong oxidizing power, its

clean nature leaving only oxygen after the treatment, and electrical generation at the site. Monitoring of ozone dose and residual levels is necessary in all these processes.

## Sampling and Calibration

Since ozone is very reactive and easily decomposes on contact with other substances, use of inert (and clean) materials such as fluoropolymers (e.g., polytetrafluoroethene (PTFE)) or glass is mandatory for sampling tubes and other parts in contact with the sample gas and water. Sample flow rate and tube diameter should be large enough to minimize decomposition loss of ozone. Particulate matter in the sample should be removed with a PTFE filter. For applications of a high ozone concentration, durable material such as stainless steel should be used.

For atmospheric ozone measurements, the sampling site should be carefully chosen to avoid any influence from the ground, plants, trees, highways, etc. Use of thermal mass-flow controllers is recommended for sampling at reduced and changing pressures (i.e., aircraft measurements). In manual wet analyses, glass midjet impingers (30 ml) are often used to strip ozone from sample air as shown in **Figure 1A**, while other types of air scrubbers with a sintered-glass diffuser have been devised. Annular denuders (**Figure 1B**), in which sample gas is passed between the narrow gap made by two concentric glass cylinders where an absorbing agent is coated, can strip ozone by diffusion without being affected by particulate matter in the sample. Air samples are generally sampled with a flow system and are analyzed at the site. For batch water sampling, the sample water should gently fill and be tightly sealed in a sampling bottle and be analyzed as quickly as possible to prevent decomposition and evaporation of ozone from the sample. Glass bottles with a sintered-glass ball are used for aeration and reabsorption of ozone as shown in **Figure 1C**. Aqueous ozone can be stabilized by cooling and maintaining pH values below 4.

While some analytical systems based on absolute methods can be calibrated statically without ozone (i.e., with standard iodine solution for iodometry), dynamic calibration using a standard ozone sample is necessary in most cases. Since ozone cannot be stored in a cylinder, an ozone generator (UV or discharge type), which is frequently standardized by iodimetry or another method, is used. Discharge-type ozone generators may produce small amounts of nitrogen oxides when air is used as a source gas. Use of purified oxygen is recommended for contamination-free and efficient ozone generation.

**Figure 1** Typical sampling apparatus for determination of ozone: (A) midjet impinger (dimensions in mm), (B) annular denuder (cross-sectional view), and (C) gas scrubbing/aeration bottle (500 or 1000 ml).

## Gaseous Ozone

Analytical methods for ozone must meet various requirements and a wide range of concentrations:  $10^{-3}$ – $10^0$  ppmv for environmental monitoring,  $10^{-2}$ – $10^2$  ppmv for biological exposure and testing, and  $10^1$ – $10^5$  ppmv for industrial applications. Automatic and dry methods are preferred rather than manual and wet methods, because of the requirements of continuous and unattended monitoring. Such instruments can provide reliable data as long as they are used and maintained properly. As there are few perfect analytical methods for ozone, an appropriate method should be chosen with a good understanding of its performance and limitations. The characteristics of major analytical methods for gaseous ozone are summarized in **Table 1**.

**Table 1** Analytical methods for gaseous ozone determination<sup>a</sup>

<i>Method</i>	<i>Analytical characteristics</i>	<i>Reagent (principle)</i>	<i>Sampling rate (1 min<sup>-1</sup>)</i>	<i>Response time<sup>b</sup> (s)</i>	<i>Detection limit (ppbv)</i>	<i>RSD<sup>c</sup> (%)</i>	<i>Remarks/interference</i>
Iodimetry (neutral buffered; photometry)	Wet, batch	1% KI in 0.2 mol l <sup>-1</sup> phosphate (pH 7.0); 352 nm	1–3	(1800)	10	2	ASTM D2912; JIS B7957; WHO. Not specific to O <sub>3</sub> . Not always accurate/ SO <sub>2</sub> , etc.
CL (gas phase)	Dry, continuous	Ethene (25 ml min <sup>-1</sup> )	1	60	1	2	EPA; JIS; WHO
CL (gas phase)	Dry, continuous	NO (168 ml min <sup>-1</sup> )	3.7	0.05–0.08	0.1	n.a.	For flux sensor
CL (aqueous phase)	Wet, continuous	10 mg l <sup>-1</sup> IDS in 2 mmol l <sup>-1</sup> phosphate (pH 7.2)	0.015	10–100	0.4	3.3	Higher sensitivity with higher sample flow rate/SO <sub>2</sub>
CL (aqueous phase)	Wet, continuous	1 g l <sup>-1</sup> eosin Y in ethylene glycol	1–7	0.14–0.7	0.2	n.a.	For aircraft measurement
UV photometry	Dry, continuous	(254 nm)	0.5–1.5	20–120	1–2	1	EPA; JIS
IR (FTIR)	Dry, continuous	(1055 cm <sup>-1</sup> )	19 800	< 300	10	n.a.	900 m path, 0.5 cm <sup>-1</sup> resolution

<sup>c</sup>Precision indicated as relative standard deviation.

## Iodimetry

One of the most obvious techniques is based upon iodimetry because it has been used as a standard or reference method in spite of its drawbacks. Ozone oxidizes iodide ion in solution:

The triiodide ion formed is determined by spectrophotometry (352 nm), volumetric titration (against sodium thiosulfate standard solution and starch as an indicator), or coulometry.

It should be noted that the reaction is not specific to ozone but proceeds with  $\text{H}_2\text{O}_2$ , nitrogen dioxide ( $\text{NO}_2$ ), peroxyacyl nitrates, and other oxidizing species, with different relative responses (this may be convenient in some cases, i.e., for measurement of the total or photochemical oxidant concentration in air). Furthermore, the ozone to iodine stoichiometry of the reaction deviates from unity depending on the pH of the solution, iodide concentration, etc., and the iodine formed may evaporate from the solution. For atmospheric applications, a neutral-buffered potassium iodide method (1% KI in  $0.2 \text{ mol l}^{-1}$  phosphate buffer,  $\text{pH } 7.0 \pm 0.2$ ) is often used amongst many variants to minimize the above instabilities. The typical detection limit is 10 ppbv (ppbv =  $10^{-9}$  mixing ratio by volume) with an air sample of 30–60 l (sampling at  $1\text{--}2 \text{ l min}^{-1}$  for 30 min). Automated instruments for continuous air monitoring are available with a countercurrent ozone absorber.

Sulfur dioxide in air dissolves in the stripping solution and gives a negative error. A chromium(VI) oxide-impregnated filter can remove  $\text{SO}_2$  from sample air. The filter is prepared as follows: a  $400 \text{ cm}^2$  portion of a glass-fiber filter is dipped in a mixture of purified water (15 ml), concentrated sulfuric acid (0.7 ml), and  $\text{CrO}_3$  (2.5 g), and is dried at  $80\text{--}90^\circ\text{C}$  for 1 h. This filter also oxidizes nitric oxide (NO) into  $\text{NO}_2$  to some extent. Although the interference from  $\text{NO}_2$  is not serious, corrections for  $\text{NO}_2$  and NO are necessary to obtain a photochemical oxidant concentration (= total oxidant –  $\text{NO}_2$ ). Nitrogen dioxide and NO give 3–5% response of equivalent amount of ozone. The relative response should be determined experimentally.

## Chemiluminescence

In chemiluminescence (CL), excess energy of a certain chemical reaction involving the species to be determined is released as light. The chemical reaction makes the CL method selective. Unlike other

photometric techniques, no incident light is necessary to obtain CL signals. This enables a high baseline stability to be attained, and hence a very low detection limit, especially for gas-phase CL methods in which background light emission is negligible.

Ozone selectively attacks olefinic double bonds in organic compounds (ozonolysis reactions). When reacted with ethene (ethylene) (Nederbragt's method), ozone gives an electronically excited methanol (formaldehyde) that emits visible light:

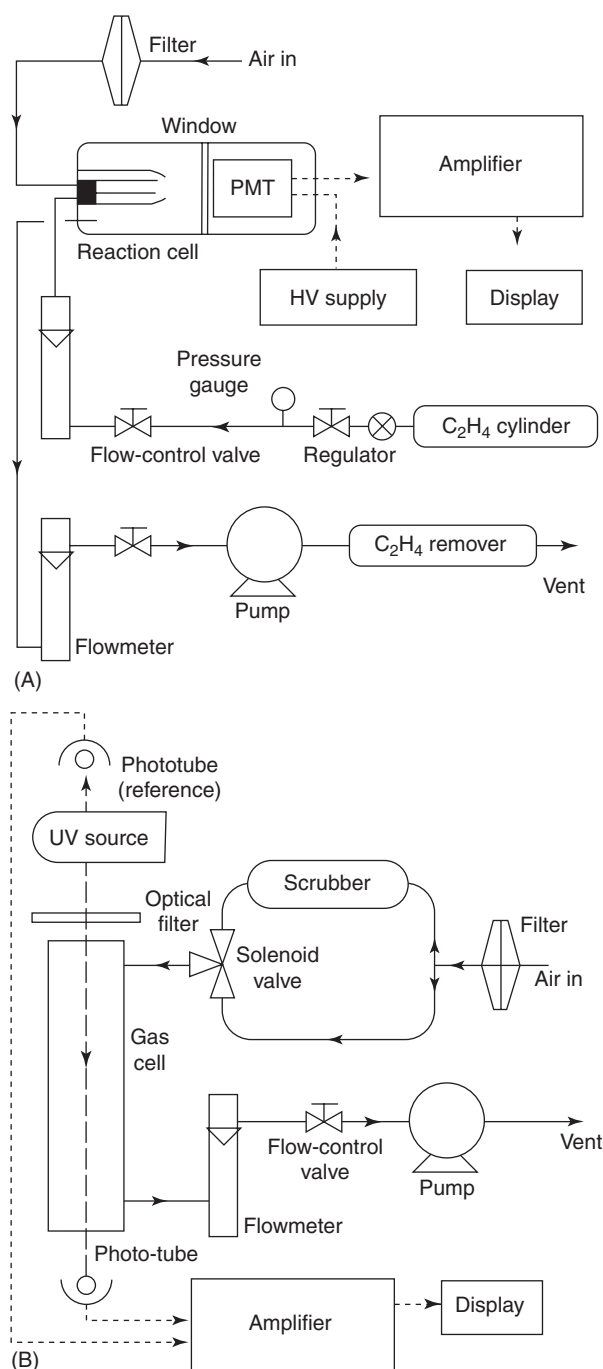

The CL (maximum at 450 nm) is conveniently detected with a photomultiplier tube (PMT). As shown in **Figure 2A**, a commercially available analyzer consists of a reaction chamber, flow control valves, and flowmeters for sample air and ethene. A coaxial double tube is used as a mixing jet in the reaction chamber. Sample air and ethene flow out from the inner tube at  $0.3\text{--}1.5 \text{ l min}^{-1}$  and the outer tube at  $20\text{--}30 \text{ ml min}^{-1}$ , respectively. Ethene is supplied from a high-pressure cylinder and unreacted ethene is removed with a catalytic converter to prevent it from polluting the environment. The ethene CL method has good selectivity and fast response, and is convenient for continuous air monitoring. However, fluctuations in the sample flow rate directly affect the measurement and care must be taken in the handling of ethene. Some instruments use ethene at a lower concentration than the flammability limit (<2.75%) to prevent possible accidents.

Another gas-phase CL method is that utilizing a reaction with NO:

This is carried out by operating a chemiluminescent  $\text{NO}_x$  analyzer (cf.  $\text{NO}_x$  analysis) at a NO excess condition. As the reaction of ozone with NO is faster and gives more intense CL than that with ethene, this method is preferred for some purposes in which a fast response is required (i.e., aircraft flux measurements). However, this CL method is subject to interference from water vapor and may contaminate the environment with NO. The ozone–NO reaction is also known as a gas-phase titration reaction, in which sample gas is mixed with a low-concentration standard NO gas and the  $\text{NO}_2$  formed in quantities equivalent to ozone is determined by an appropriate method. While CL reactions of ozone with other alkenes, alkyl sulfides, phosphine, arsine, and stibine

**Figure 2** Schematic diagrams of (A) chemiluminescent ozone analyzer and (B) UV photometric ozone analyzer.

have been reported, none of them have been utilized as analytical methods to date.

There are some liquid-phase CL methods using dye compounds as a reagent. Ozone can be measured either by passing sample air into an ethanolic solution of rhodamine B and gallic acid or using a rhodamine B impregnated silica disk. CL methods with eosin Y and with coumarin 47 are also reported for rapid

response. So far these methods have been used for research purposes only because of insufficient selectivity and long-term stability. The mechanism involved in ozone-dye CL is not yet clear.

Some ozonolysis reactions that take place in the liquid phase also give CL. An aqueous solution of indigo-5,5'-disulfonate (IDS, indigo carmine), which is used in the spectrophotometric determination of ozone as described below, emits light at 430 nm on contact with ozone reaction [VII]. This method is more selective than other liquid-phase CL methods. Some reducing gases like  $SO_2$  interfere, but that is tolerable for usual atmospheric measurements. The reagent solution can be recycled for long time measurements. The IDS-CL method gives a sensitivity three orders of magnitude higher than the IDS spectrophotometric method on the basis of sample amounts of equal portions.

### Direct UV Spectrophotometry

Ozone exhibits a strong absorption band centered at  $\sim 255$  nm (Hartley band). The maximum absorption coefficient (base 10) is  $135 \text{ cm}^{-1}$ . This absorption is conveniently measured with a low-pressure mercury lamp that has an intense emission line at 253.7 nm. Using a mercury lamp, bandpass filter, gas cell 40–60 cm long, and phototube, detection of ozone down to 1 ppbv is possible. Another phototube equipped in the analyzer corrects the instability and aging of the light source. Commercially available instruments (Figure 2B) avoid interferences from other UV-absorbing species by generating reference (zero) gas internally: a solenoid valve switches the sample to a metal oxide catalyst layer at a certain time interval and the catalyst selectively decomposes ozone in the sample gas. However, ppmv levels of aromatic hydrocarbons give positive responses to the instrument.

The UV photometric ozone monitor is relatively maintenance free except for periodic calibration by iodimetry and changing of the inlet filter and catalyst. Hence, UV photometry is suitable for continuous monitoring of atmospheric ozone and has been adopted as a standard method along with the ethene-CL method in major counters. UV ozone monitors with higher concentration ranges (up to 10 vol%) are also available. In high-concentration ozone measurements, ozone-free reference should be prepared separately for calibration, because of insufficient activity of the catalyst for ozone destruction. For a humid air sample, a water trap (or humidifier) is necessary.

### Electrochemical Methods

Although ozone at high concentrations can be determined by direct electrochemical reduction, reactions [I] and [II] ( $\text{Br}^-$  in place of  $\text{I}^-$ ) are generally employed to increase sensitivity and to eliminate interference from oxygen. Electrochemical methods are sensitive enough for atmospheric ozone and can be operated continuously. However, these methods have disadvantages similar to iodimetry: they are not specific to ozone and are subject to interference from other oxidizing and reducing substances. Coulometric methods are described here, although a number of potentiometric and amperometric methods have been reported.

A galvanic cell-type (Hersch cell) coulometer consists of a platinum (Pt) cathode, KBr (or KI) electrolyte (stripping solution), and active carbon anode. When air containing ozone is bubbled into the solution, the bromine (or iodine) liberated by the ozone is reduced at the Pt cathode and hydroxide ion discharges at the carbon anode:

The current between the electrodes directly represents the concentration of ozone in the solution. Commercial instruments have internal  $\text{Br}_2$ -generating electrodes for calibration without ozone.

In Brewer–Milford-type coulometry, a potential of 0.2–0.3 V (lower than the decomposition potential of iodide solution) is applied between two Pt electrodes. Polarization current is observed until the surface of the cathode is completely covered with hydrogen:

When iodine is formed in the solution by reaction with ozone, some of the hydrogen film on the

electrode is removed as:

Then, the current again from reaction [X] is observed, which corresponds to the ozone concentration. The solution can be circulated after passing an adsorbent column. The air-monitoring data obtained with these coulometric ozone analyzers do not always coincide with those with iodimetry–photometric detection analyzers. This may be attributed to the difference in responses to other oxidants such as  $\text{NO}_2$ .

### Infrared Spectrophotometry

Infrared spectrophotometry of ozone based on the principal absorption band near  $9.5\text{ }\mu\text{m}$  is relatively free from interference by the bands of other atmospheric constituents. However, a long optical path is necessary for detection of atmospheric ozone. A White cell (multiple reflection cell, 10–1000 m path) combined with a Fourier-transform infrared (FTIR) spectrometer (spectral resolution of  $1\text{ cm}^{-1}$  or better) with a HgCdTe detector is often used in multi-component air-monitoring and smog chamber experiments.

Recently, very sensitive and selective measurements became possible by tunable diode laser absorption spectroscopy (TDLAS). Diode lasers that lase in the mid-infrared region give extremely high resolution ( $3 \times 10^{-4}\text{ cm}^{-1}$ ) and can tune the emission line to one of many vibration–rotation bands by changing the laser temperature and current (10–100 K, 0.1–2.0 A). The TDLAS measurement is usually carried out at reduced pressure to avoid band broadening due to molecular collision. Practically interference-free measurements are possible with a typical detection limit of sub-ppbv levels (100 m path, at 25 Torr), although the TDLAS system is still expensive and under development.

### Spectrophotometric Methods

Indigo-5,5'-disulfonate (or trisulfonate) reacts with ozone as described in the CL section. The blue color of IDS disappears on reaction with ozone and the decrease in absorbance at 610 nm is measured. As the molar absorptivity ( $\sim 2 \times 10^4\text{ mol l}^{-1}\text{ cm}^{-1}$ ) depends on the brand and batch of commercially available IDS probably due to impurity, the apparent reaction stoichiometry of IDS to ozone is not exactly unity. However, the stoichiometric ratio is reproducible when the same IDS reagent is used throughout. Nitrogen dioxide interferes positively by 6% of the mass of  $\text{NO}_2$ , but  $\text{SO}_2$ ,  $\text{NO}$ ,  $\text{HF}$ ,  $\text{H}_2\text{S}$ ,  $\text{H}_2\text{O}_2$ , and peroxyacetyl nitrate do not interfere. Sampling time

required can be estimated during sampling by noting decolorization.

In annular denuder sampling, potassium iodide (20 g KI in 10 ml of deionized water + 10 ml of 10% glycerol in methanol), phenoxazine (0.4 g in 20 ml of acetone), and 4-allyl-2-methoxyphenol (eugenol, 10% in methanol) are used as absorbents. The third absorbent releases formaldehyde by ozonolysis, which is collected with another downstream denuder coated with 2,4-dinitrophenylhydrazine (0.5% in acetonitrile containing 1% phosphoric acid).

### Thermometry

A large amount of heat is released when ozone is decomposed into oxygen ( $\Delta H = 143 \text{ kJ mol}^{-1}$ ). The sensing device has two thermistors that form a part of a bridge circuit and some catalyst (e.g., hopcalite, a mixture of manganese and copper oxides) coated on one of the thermistors to decompose ozone. When sample air containing ozone is passed through the cell, ozone heats catalyst-coated thermistor, and thus a signal related to ozone concentration is obtained. Devices for both atmospheric and industrial ozone have been designed.

### Sensors

There is some confusion in defining the term 'sensor', and only small semiconductor sensors are described here. Membrane electrode-type analyzers are discussed in the Aqueous Ozone section. Semiconductor ozone sensors based on field effect transistor (FET) are now commercially available. In this sensor, the gate of a FET is replaced with n-type semiconductor metal oxide (e.g.,  $\text{SnO}_2$ ) thin film. When electrophilic ozone is adsorbed on the film, an electric field is induced in the device, resulting in a change in the current between the source and drain terminals. The device is maintained at a high temperature so that water vapor and other substances do not affect the measurement. Sensitivity and selectivity can be optimized by changing the film thickness, the dopant in the film as the donor and its concentration, operating temperature, etc. The characteristics of the sensor can be precisely controlled by semiconductor production technologies. Moreover, producing different sensors on a tip, it is possible to provide a multisensing device. This sensor is small but has fairly good sensitivity and accuracy for quick measurements.

### Other Methods

In the early stage of air pollution studies, rubber cracking due to ozone was utilized for semiquantitative determination of ozone. Manometric methods based on the pressure increase after catalytic decomposition

as described in thermometry are also proposed for high ozone concentrations.

Redox reactions with ozone other than iodimetry are reported with different detection methods. Iron(II) reacts with ozone stoichiometrically in an acidic medium (pH 2.0). The resultant iron(III) forms a red complex with potassium thiocyanate, or the excess iron(II) is determined with permanganate, 1,10-phenanthroline derivatives, etc. Arsenic(III), manganese(II), and copper(II) can also be used as reagents for ozone determination. Analytical methods based on ozonolysis reactions with 1,2-bis(4-pyridyl)ethene, 1,1-diphenylethene, indigo, dimethoxystilbene, and diacetyldihydrolutidine have been reported. Other organic reagents for ozone include phenolphthalein, *N*-phenyl-2-naphthylamine, aromatic isocyanates, diphenylaminesulfonate, and *o*-tolidine.

Disposable detector tubes are available for simple and easy detection of ozone. It is based on the indigo-ozone decolorization reaction. In the glass tube is an adsorbent layer containing indigo. Ozone is determined from the length of the layer decolorized. Sampling is done with a special hand pump. Tubes for several concentration ranges are supplied: 0.05–3, 2.5–100, and 25–1000 ppmv, and 0.02–4  $\text{mg l}^{-1}$  (aqueous ozone after purging dissolved ozone).

## Remote Sensing

With a growing interest in the global atmospheric environment, remote sensing techniques are regarded as a most powerful and efficient way of monitoring stratospheric ozone. Some of the methods described can be applied to tropospheric ozone measurements as well.

### Dobson Spectrophotometer

This instrument is a differential spectrophotometer observing two closely separated wavelengths with different absorption coefficients for ozone in order to eliminate the scattering effect and interference from other atmospheric constituents. When the sun is used as a light source, the Dobson spectrophotometer gives the total ozone concentration in that air column. One of the following pair of wavelengths (nm) is selected from the structured Huggins bands: (325.4, 305.5), (329.1, 308.8), (332.4, 311.4), and (339.8, 317.8). Results are presented by the Dobson unit (equivalent to  $10^{-3} \text{ cm}$  thickness of pure ozone at standard temperature and pressure). Accuracy is generally better than 2% (as a standard error).

### Differential Absorption Lidar

In the differential absorption lidar (DIAL) technique, the average gas concentration over some range is determined by monitoring the laser backscatter light intensity for wavelengths tuned on and off an absorption peak of the gas of interest. The backscattered light is received with a telescope and PMT. The concentration can be determined from the ratio of the signals at the on/off wavelengths.

In NASA's airborne DIAL system, for example, these wavelengths are tuned to 286 and 300 nm for ozone ranging using frequency-doubled tunable dye lasers pumped with neodymium: yttrium–aluminum–garnet lasers or excimer lasers. Light of longer wavelength is also transmitted to correct the data for aerosol distribution. Typical precision and accuracy of the *in situ* measurements are 2 and 10%, respectively. Airborne DIAL systems can operate in both nadir and zenith modes with a vertical resolution of 50–200 m through the entire troposphere. They have been applied to the observations of the antarctic ozone hole, and other areas. An infrared DIAL system for ozone has also been developed using transverse excited atmospheric carbon dioxide lasers.

### Instruments Carried by Satellites

The solar backscatter UV instrument used by NASA called TOMS (total ozone mapping spectrometer) on the Nimbus-7 satellite provides total ozone maps by nadir viewing. The striking pictures of the Antarctic ozone hole have proved its power. An earth-limb scanning UV–visible grating spectrometer, SAGE (stratospheric aerosol and gas experiment) also operated by the NASA, observes the sun to the side through the atmosphere. This instrument can measure vertical profiles of ozone and other species with 1 km resolution and an accuracy of 5%. Instruments based on FTIR are also being developed for satellite measurements.

## Aqueous Ozone

Most of the analytical methods for gaseous ozone can be applied to aqueous ozone. Wet analytical methods readily accept water samples. After aeration of water samples, aqueous ozone can be determined either by dry methods or by wet methods that are subject to interference from coexisting solutes. However, the transmission efficiency of ozone from one solution to another must be considered. Analytical methods for aqueous ozone are summarized in Table 2.

### Redox Titration

Iodometry is also used as a standard method for aqueous ozone. Ozone in a water sample (800 ml) is transferred to a 400-ml portion of 2% KI absorbing solution by aeration with  $0.2\text{--}1.01\text{ min}^{-1}$  purified air (or  $\text{N}_2$ ) stream. The solution is acidified with  $0.5\text{ mol l}^{-1}$  sulfuric acid (20 ml) and is then titrated with  $2.5\text{ mmol l}^{-1}$  standard sodium thiosulfate solution to a starch endpoint. A blank test is necessary for accurate measurements.

In addition to iodometry, an arsenite solution (pH 6.5–7.0) is used as titrant for determination of aqueous ozone. The excess arsenic(III) is back-titrated with a standard iodine solution. This method is reported to be more selective for ozone than iodometry.

### UV–Visible Spectrophotometry

Direct measurement of UV absorbance is applicable to aqueous ozone. Unfortunately, the molar absorptivity at 260 nm has not yet been exactly established:  $3290\text{ mol l}^{-1}\text{ cm}^{-1}$  is considered to be reasonable out of the reported values ranging from 2900 to  $3600\text{ mol l}^{-1}\text{ cm}^{-1}$ . For real aqueous ozone samples, special care should be taken to avoid interferences from coexisting substances. Background absorbance can be determined after destruction of the residual ozone with an excess of nitrite or butenol.

Indigosulfonates are used as reagents for spectrophotometric determination of ozone. The decrease in absorbance at 610 or 600 nm after mixing with the aqueous sample is measured with disodium indigo-5,5'-disulfonate (IDS) or tripotassium indigo-5,5',7-trisulfonate (ITS). The residual absorbance of the mixture (at pH 2.0) is stable over several hours. The indigo method is not subject to interference from chlorite and chlorate ions and  $\text{H}_2\text{O}_2$ , while chlorine, bromine, iodine, and permanganate interfere to some extent. The interference from chlorine can be masked with malonic acid ( $0.5\text{ g l}^{-1}$ ).

A flow injection analysis based on the indigo method with a gas diffusion cell has been reported for interference-free automatic measurement. A microporous PTFE membrane is used as a septum in the cell. Silicone membranes with higher permeability give irreproducible results. When the aqueous sample is switched to one compartment of the gas diffusion cell, the reagent solution containing ITS remains in the other compartment to give higher sensitivity. After this sampling period (10–30 s), the reagent solution is sent to a spectrophotometer. The detection limit and sample throughput are  $30\text{ ng ml}^{-1}$  and  $65\text{ h}^{-1}$ , respectively. It can be said that the gas diffusion cell performs the aeration–reabsorption procedure on a microscale.

<sup>a</sup> Key: CL, chemiluminescence; UV, ultraviolet; IDS, indigo-5,5'-disulfonate; ITS, indigo-5,5',7-trisulfonate; ACVK, Acid Chrome Violet K (Alizarin Violet 3R); n.a., not available.

<sup>b</sup> For batch methods, sampling time (s) is shown in parentheses.

<sup>c</sup> Precision indicated as relative standard deviation.

As in the case of indigosulfonates, Alizarin Violet 3R (Acid Chrome Violet K) loses its color on reaction with ozone and chlorine dioxide. Ozone can be determined from the decrease in absorbance at 548 nm after mixing with a sample solution. This method is less sensitive than the indigo methods. Chlorine, hypochlorite, chlorite, and chlorate do not interfere. While chlorate(III) can also be determined by this method, it does not coexist with ozone in treated waters.

Ozone oxidizes bis(terpyridine)iron(II) into the corresponding iron(III) complex, as well as the bipyridine and 1,10-phenanthroline complexes of iron(II). The first complex is more stable than the latter complexes in a slightly acidic medium. Judging from the molar absorptivity of the iron(II) complex ( $1.1 \times 10^4 \text{ mol l}^{-1} \text{ cm}^{-1}$ ) and reaction stoichiometry (complex/ $\text{O}_3 = 2$ ), this method may be as sensitive as the indigo method.

Spectrophotometric methods using *o*-tolidine and *N,N*-diethyl-1,4-phenylenediamine are not specific for ozone and the colors developed are unstable with time.

### Electrochemical Methods

Amperometric methods using a gas-permeable membrane provide selective and sensitive measurement for aqueous ozone. Such an electrode system consists of a microporous PTFE (or polypropylene) membrane (25–100  $\mu\text{m}$  thick), gold cathode, supporting electrolyte, reference electrode (in a three-electrode system), and counterelectrode. The membrane covers the gold cathode tip and a capillary film of electrolyte. An applied voltage of +0.6 V (versus Ag/AgCl) is adopted for selective reduction of ozone. Use of the membrane reduces the current sensitivity to ozone, but improves selectivity greatly. Relative responses to possible interfering species such as  $\text{Br}_2$ ,  $\text{ClO}_2$ ,  $\text{HOBr}$ ,

$\text{HOCl}$ ,  $\text{NCl}_3$ , and  $\text{H}_2\text{O}_2$  were less than 2%. Three-electrode-type instruments with pulsed operation (100 ms pulse duration and 5 s interval) provide much higher sensitivity, because the ozone concentration builds up in the membrane layer during the interval between pulses and a transient current is obtained consuming the ozone in the layer when a pulse is applied. These sensor-like instruments are now commercially available.

Water-borne coatings are hardly new. Emulsion paints, mostly used in domestic decorating, have been in use since the 1950s; today they account for around a third of the United Kingdom's total paint production. Water-based coatings can be formulations made from water-soluble polymers or dispersions of polymer particles in water. The vast majority of water-based coatings used for domestic and industrial purposes today are of the dispersion type because it is easier to obtain high solids at application viscosities and emulsion polymers dry quickly to give tough films.

This article will concentrate on the synthesis and characterization of water-based dispersions. Analytical and test methods that find particular use with water-based coatings will be detailed.

### Production

Dispersions are sometimes called emulsions because of the method of synthesis, but this does not signify that the final product is a liquid-in-liquid dispersion. Most commercial formulations are solid polymer dispersions and should more accurately be called lattices (or latexes).

A fully formulated water-borne dispersion paint is a much more complex mixture than a solvent-borne coating. A selection of materials that may be present is listed below:

- polymer particles,
- ionic/nonionic surfactant,
- coalescing solvent,
- corrosion inhibitor,
- antifreeze,
- biocide,
- freeze/thaw stabilizer,
- water,
- pigment/extender,
- thickening agent,
- pigment dispersant,
- antifoaming agent,
- preservative,

- neutralizing agent, and
- surface tension depressant.

Emulsion polymerization is the process in which vinyl and acrylic monomers undergo addition polymerization in water in the presence of surfactant and water-soluble initiators. Stable polymer dispersions are formed with particle sizes in the range of 0.1 to 0.5  $\mu\text{m}$ .

There are two stages involved in a typical emulsion polymerization. In the seed stage, a mixture of water, surfactant, and colloid is first heated to the reaction temperature (85–90°C). Next, 5–10% of the monomer mixture with a portion of the initiator is added. At this point the reaction mixture contains monomer droplets stabilized by surfactant, some dissolved monomer, the initiator, and surfactant (in solution and in micelles). The initiator breaks down to produce radicals, when heated and these initiate the polymerization of the dissolved monomers. Growing polymer chains eventually enter a micelle, initiating reaction of the monomer inside. If a second growing polymer enters the micelle, termination can occur.

During the seed stage, micelles of monomer are converted to latex particles, which are stabilized by surfactant. Most of the particles present in the final latex are formed in the seed stage and polymerization will have proceeded to 10% or 15% completion.

In the feed stage, the remainder of the monomer and initiator are added to the reaction mixture. Monomer diffuses from droplets through the aqueous phase to the growing polymer particles and propagates the polymerization. Radicals can also enter the particles, causing termination or re-initiation of polymerization. As the particles become larger, more surfactant from the aqueous phase is absorbed onto the surface to stabilize the dispersion.

Before cooling, a further shot of initiator may be added to ensure that all monomer has been converted to polymer.

It is more difficult to control emulsion polymerization than normal solution acrylic polymerization. Vigorous stirring is required to disperse the reactants and later to allow efficient extraction of heat through the reactor vessel walls. However, the mixture may be shear-sensitive, so excessive agitation must be avoided. Too much heating can have adverse effects, so it is usual to heat the reactants in the initial stages but apply cooling in the later stages to maintain a constant temperature.

Alkyd emulsions are made by dispersing a liquid alkyd resin in water by mechanical means. Alkyds are polyester resins modified with fatty acids. They are produced by reacting fatty acids with a polyol such as glycerol (1,2,3-trihydroxypropane) and a dibasic acid such as orthophthalic acid

(benzene-1,2-dicarboxylic acid). To facilitate emulsification, the acid content is increased by using some tribasic acid such as trimellitic (1,2,4-benzene tricarboxylic acid). Alkali, ammonia, or amine is then added to partially neutralize the resin.

Alkyd resins undergo autoxidation after application, which results in a buildup of molecular mass, improving the coating's protective properties. Autoxidation is catalyzed by the addition of small amounts (0.5%) of metal driers, such as cobalt, in the form of a metal naphthanate or octoate. The activity of the metal drier is inhibited by the presence of amine and by hydration in aqueous systems.

The latest alkyd emulsions contain only resin, water, and nonionic surfactant. High shear rates are used to disperse the resin so that high acid values and amines are not required. Drying is still inhibited to some extent as some of the cobalt resides in the aqueous phase. For this reason more dryer is required than for solvent-based systems.

## Chemical Composition

### Monomers

The monomer composition must be chosen carefully as it will affect the properties of the final coating and the film-forming ability of the latex. The minimum film-forming temperature (MFFT) is defined as the lowest temperature at which the latex particles will coalesce to give a clear film. It is related to the glass transition temperature ( $T_g$ ) of the polymer but is also influenced by the presence of other materials such as coalescing solvents, plasticizers, and surfactants. In order that the latex particles can coalesce and form a continuous film on application, the MFFT must be below the temperature at which film formation will occur. For domestic paints an MFFT of below 10°C is required.

Emulsions can be formulated with only hard monomer and plasticized at a later stage, but it is normal to internally plasticize the emulsion by copolymerizing some soft monomer. Vinyl acetate plasticized with an acrylate such as butyl or ethylhexyl acrylate, or a dialkyl maleate, are common combinations. Other hard (high  $T_g$ ) monomers include methyl methacrylate, styrene, and vinyl chloride. Soft monomers include Vinyl Versatate<sup>TM</sup> (Shell Chemicals), ethylene, and vinylidene chloride (**Figure 1**).

The exact choice of monomers is determined primarily by the properties required in the final coating. Acrylic polymers tend to give high-quality coatings, whereas formulations based on vinyl acetate plasticized with butyl acrylate have good

**Figure 1** Common monomers used in emulsion polymerization.

chalking resistance but poor resistance to alkalis and hydrolysis.

Exterior durability is enhanced by inclusion of methacrylates and acrylates. Styrene, methacrylic acid, and acrylic acid increase hardness in the coating, while flexibility is conferred by ethyl, butyl, or ethylhexyl acrylate. Stain resistance is improved when short-chain (meth)-acrylates are used and acrylics also impart improved resistance to water. Solvent and grease resistance can be improved by copolymerizing acrylonitrile, methacrylamide, and methacrylic acid.

Thermosetting latices contain functional groups, which can be used to cross-link the coating after film formation usually by heating. These polymers normally contain hydroxy monomers that can be cross-linked with materials such as water-soluble melamine derivatives, urea-formaldehyde, or phenolic resins. Alternatively, epoxy groups in the latex can be cross-linked with amines.

Emulsion systems for anticorrosive coatings are usually copolymers of vinylidene chloride, vinyl chloride, and an alkyl acrylate or methacrylate. Relatively small amounts of surfactant and colloid are used in order to minimize water sensitivity in the dried coating. Flash rusting inhibitors such as ammonium chromate/dichromate or alkali metal nitrate/nitrites may also be added.

Paints for cathodic electrodeposition are usually emulsions of amine-modified epoxy resins with a

positively charged particle surface. The particles are destabilized when an electric current is applied using a pair of electrodes dipped into the emulsion. The particles are deposited on the cathode, which is formed by the substrate to be coated.

### Initiators and Activators

Common initiators for emulsion polymerization are compounds containing a peroxide bond, such as hydrogen peroxide and sodium peroxodisulfate. The most commonly used are the latter type, which contribute significantly to latex stabilization by introducing terminal sulfate groups on each polymer chain formed in the initial solution polymerization.

The rate of dissociation into radicals is accelerated by addition of reducing agents such as sodium hydrogensulfate (NaHSO<sub>3</sub>), sodium disulfite (metabisulfite) (Na<sub>2</sub>S<sub>2</sub>O<sub>5</sub>), sodium thiosulfate (Na<sub>2</sub>S<sub>2</sub>O<sub>3</sub>) or sodium formaldehyde sulfoxylate (NaHSO<sub>2</sub> · CH<sub>2</sub>O · 2H<sub>2</sub>O). Activators are also added in the form of iron salts such as iron(II) sulfate (FeSO<sub>4</sub> · 7H<sub>2</sub>O) or ammonium iron(II) sulfate (Fe(NH<sub>4</sub>)<sub>2</sub>(SO<sub>4</sub>)<sub>2</sub>).

### Surfactants

The van der Waals attraction between two atoms is very short range, acting over a few tenths of a nanometer. For latex particles, however, each atom or molecule of one particle attracts every atom or molecule in the other particle. The net attraction is long range and of considerable strength. At practical particle concentrations, dispersions would be stable for only a few seconds if they were not stabilized. The attractive force between latex particles can be overcome by electrostatic or steric stabilization.

‘Electrostatic stabilization’ is achieved by producing a charged surface on the particles. The electrostatic component can be due to charge on the particle surface or charge associated with the stabilizing moieties. This produces a layer of opposite charge in the dispersion medium and this electric double layer causes repulsion of the particles. ‘Steric stabilization’ is achieved by attaching macromolecules to the surface of the particle either by grafting or by physical adsorption.

The most common method of stabilizing latex particles is by addition of mixed anionic and non-ionic surfactants. The key property of a surfactant is that it possesses chemically dissimilar groups: one hydrophobic and one hydrophilic. The hydrophobic group is physically adsorbed onto the polymer latex particle while the hydrophilic portion extends into the aqueous phase. It is the hydrophilic groups that provide the stabilization.

Anionic surfactants are typically alkali metal salts of long-chain carboxylic or sulfonic acids, for example sodium di-2-ethylhexyl sulfosuccinate (Aerosol OT).

The best steric stabilizers are amphiphathic block or graft copolymers such as poly(oxyethylene lauryl ether) ( $M_r \approx 1200$ ). Commercial nonionic surfactants are classified according to the hydrophilic-lipophilic balance (HLB), which scales the relative solubilities of the two components in aqueous and nonaqueous media. The need for the anchor part of the stabilizing molecule can be eliminated if the stabilizing moieties can be covalently bonded to the latex particles.

### Coalescing Aids

In most cases low-volatility organic coalescing agents such as Texanol<sup>TM</sup> (2,2,4-trimethyl-1,3-pentanediol monoisobutyrate, Eastman Chemical Co.), ethylene/propylene glycols, or benzyl alcohol are added to cause high  $T_g$  polymers to coalesce at room temperature. Hydrocarbons are effective when the copolymer contains a substantial fraction of higher alkyl monomer such as ethylhexyl acrylate.

For domestic paints the MFFT is typically in the range 0–10°C but lower MFFTs are required with highly pigmented and extended finishes. For industrial applications the MFFT may be above room temperature but the coating will require heating after application to produce fully coalesced films.

To provide good film properties the  $T_g$  of the final film must be raised above ambient temperatures by evaporation of coalescing solvent for thermoplastic systems or cross-linking in thermosetting formulations.

### Colloids

Colloids or water-soluble polymers are added to the formulation to assist with particle size control and to modify the rheology of the final paint. They can be water-soluble polymers such as poly((meth)acrylic acid) and its copolymers, poly(vinyl alcohol) or substituted celluloses such as hydroxyethylcellulose.

Associative thickeners are low-molecular-mass water-soluble polymers with at least two hydrophobes such as hydrophobically modified ethylene oxide-urethane block copolymers (HEUR) or hydrophobically modified hydroxyethylcellulose (HMHEC). The hydrophobes can associate with themselves or with hydrophobes on surfactant, cosolvent, latex, and pigment. This sets up a loose network that is sensitive to mechanical disturbance but re-forms quickly. The result is that pigment settling and film sag are reduced because the network structure increases the low shear viscosity, but the formulations show easy

brushing and improved leveling because the network breaks down under high shear.

### Pigments and Extenders

A paint is made by mixing the binder, in this case the latex, with pigment. The pigment is initially dispersed in water with a surfactant and the slurry added to the latex and mixed further. The amount of pigment used is characterized by the pigment volume concentration (PVC), which is defined as

$$\text{PVC} = \frac{\text{volume of pigment}}{\text{volume of pigment and binder}} \times 100\% \quad [1]$$

For a gloss emulsion paint the PVC will be  $\sim 20\%$ , but for a matt emulsion finish the PVC will be much higher.

The most common white pigment used in coatings is titanium dioxide ( $\text{TiO}_2$ ), though small quantities of antimony oxide ( $\text{Sb}_2\text{O}_3$ ), zinc oxide ( $\text{ZnO}$ ), and lithopone ( $\text{ZnS} + \text{BaSO}_4$ ) may still be used. The surface of  $\text{TiO}_2$  pigments is photoactive and can initiate reactions that would lead to the breakdown of the organic binder. For this reason the surface is coated with small amounts of oxides of aluminum and/or silicon and/or zirconium. A typical  $\text{TiO}_2$  pigment for a water-based coating would contain 1–4% aluminum oxides, 0–6% silicon oxides, and 0–1% zirconium oxides.

Extenders may be added to reduce the price of paint or to modify the appearance by reducing gloss. Some common extenders are barium sulfate, calcium carbonate, silica, talc ( $\text{Mg}_3\text{H}_2(\text{SiO}_3)_4$ ), and china clay ( $\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 2\text{H}_2\text{O}$ ).

It is more difficult to achieve good pigment dispersion in water-based than in organic solvent-based systems. Good dispersion is important to obtain high gloss and opacity and good barrier properties in the final coating. Pigment flocculation can be caused by soluble polymers or ionic impurities in the aqueous phase. Some anticorrosive pigments must be slightly soluble to be effective.

Even if the dispersion is stable, flocculation can occur during drying of the film as the concentration increases. For these reasons the choice of dispersing agent (surfactant) for the pigment is critical. There are several types of commercial dispersants available including anionic polyphosphate (Calgon), sodium salts of polycarboxylic or acrylic acids, or amino alcohols.

Typical formulations for two types of domestic water-based coatings are shown in Table 1.

Coatings made from water-based dispersions suffer several deficiencies when compared to

**Table 1** Typical formulations for domestic water-based coatings

	<i>Gloss emulsion weight (%)</i>	<i>Water-based undercoat weight (%)</i>
TiO <sub>2</sub>	21.0	25.0
Extender		14.5
Acrylic latex (50% solids)	56.0	26.0
Antifoam	0.2	0.2
Pigment dispersant	0.2	0.25
Coalescing solvent	10.0	1.0
Biocide	0.5	0.5
Ammonia	1.0	1.0
Thickener	0.2	0.25
Water	10.9	31.3

solvent-borne coatings. Incomplete coalescence and pigment flocculation affect the film's barrier properties and reduce gloss. Temperature and humidity strongly influence the drying characteristics. At low humidity, drying can be so rapid as to cause craters to appear in the final film; at high humidity, drying can be so slow that severe sagging occurs.

Because of water's high latent heat of vaporization, as much as four times more energy is required to force-dry or stove water-borne coatings compared to conventional coatings.

On ferrous substrates, flash rusting may be a problem and penetration into porous substrates is poorer than with solvent-borne coatings, which can lead to premature failure especially on a chalky surface.

Finally, biocides may be required because many components of a water-borne coating are nutrients for microorganisms.

## Analytical Techniques

Routine methods of chemical analysis can be applied to water-based coatings. For example, the nature of the binder can be determined by infrared spectroscopy. Water-resistant plates, such as KRS5 or zinc selenide, must be used if capillary films are cast from the aqueous dispersion. Dried films can be analyzed by surface-sensitive techniques such as attenuated total reflection (ATR) or photoacoustic spectroscopy (PAS). Both these techniques require the use of Fourier transform infrared (FTIR) instruments to obtain spectra in a reasonable time.

The nature and amount of volatile organic components, such as coalescing solvents or plasticizers and remaining monomer, can be measured by gas chromatography coupled with mass spectrometry (GC-MS).

## Particle Size

A fundamental property of water-based dispersion paints is the particle size of the latex and pigment particles. There are several methods available for measuring particle dimensions and size distributions but the methods used are determined by the size ranges involved. Latex particles are submicrometer particles with diameters typically within the range 100–500 nm. For the pigment titanium dioxide, particles are always ~250 nm as this size gives the maximum light-scattering and hence opacity.

Sedimentation techniques are amongst the oldest methods of particle size measurement. Sizes are derived from the rate of settling of particles under the action of gravitational or centrifugal forces. One sedimentation technique is the disk centrifuge, which is used to measure particles in the range 0.1–50 µm.

The disk centrifuge consists of a transparent disk-shaped container that spins at a speed of 500–15 000 rpm. The particles to be measured are introduced onto the spinning disk using a so-called buffered line start method in which a spin fluid is made up so that a density and viscosity gradient is created within it. This prevents 'streaming' or 'settling' of the particles in the spin fluid.

Measurements are made using X-rays rather than visible radiation because X-rays are absorbed in direct proportion to the mass of particles between the source and detector. The diameter of a particle can be calculated by measuring the time  $t$  for the particle to reach a position  $r_t$  from a starting position  $r_i$  using a modified form of Stokes' law:

$$t = \frac{18\eta \ln(r_t/r_i)}{w^2 d^2 \Delta p} \quad [2]$$

where  $\eta$  = the viscosity of the spin fluid,  $w$  = the centrifugal speed of the disk, and  $\Delta p$  = the difference in density between the particle and spin fluid.

The technique is very sensitive to differences in particle size as the rate of sedimentation is proportional to the square of the particle diameter.

Direct observation of particles can be achieved using scanning electron microscopy (SEM) or transmission electron microscopy (TEM). This can give very accurate measurements as monodisperse particles can be used as standards but the process can be time-consuming. It is important that the measured particles are representative of the whole sample, so many particles, preferably from different micrographs, must be measured. This is possible by automating the measurements using image-analysis systems that are now available for personal computers.

Light-scattering methods can be used to measure the size of dispersed latex and pigment particles.

Scattering of radiation originates in the oscillating dipoles of polarizable particles induced by the oscillating electric field of an incident light beam. The intensity of scattered radiation is dependent upon the ratio of the particle size to the wavelength of the incident radiation and the refractive index difference between the particle and the suspending medium.

In photon correlation spectroscopy (PCS), light from a low-power helium–neon laser is focused on a temperature-controlled sample cell and light scattered at a known angle to the cell is detected by a photomultiplier. The random motion of particles in the laser beam causes fluctuations in the intensity of the scattered radiation that can be analyzed with a digital correlator. The smaller the particle the more rapid the fluctuations due to more rapid motion. The time dependence of the fluctuations is used to generate a correlation function, which is the sum of fluctuations caused by all particles. Autocorrelation theory can then be used to determine the diffusion coefficient,  $D$ , for the particles and hence the particle's hydrodynamic diameter,  $S$ , from the Stokes–Einstein equation:

$$D = \frac{kT}{3\pi\eta S} \quad [3]$$

where  $k$  is Boltzmann's constant,  $T$  is temperature, and  $\eta$  is the viscosity of the suspending medium.

The information is presented in the form of an intensity distribution, with the mean particle size and a measure of the polydispersity that is related to the variance in the average diameter (Figure 2).

PCS gives very quick, reliable measures of particle sizes for monodisperse systems but problems can arise in systems containing two distinct sizes of

particles. Separation into two peaks is only possible when the size ratio approaches 2:1.

The practical size range covered by PCS is 10–3000 nm. For larger particles, laser diffraction can be used up to sizes of 600  $\mu\text{m}$ . The principle behind laser diffraction is that diffraction from small particles is greater than from large particles. The diffraction of a laser beam through small angles is measured, from which the particle size can be calculated. The scattering angle is inversely proportional to the particle size and the intensity at each angle is the sum of scattering from particles of a given size.

### Zeta Potential

Photon correlation spectroscopy can also be used to measure electrophoretic mobility and zeta potentials of suspended particles. The sample is subjected to an electric field that causes charged particles to migrate to one of the electrodes. Two coherent laser beams intersect within the sample, giving rise to a series of interference fringes. The fluctuations in the signal intensity are analyzed in the manner described above to calculate the mobility distribution of the particles and then the potential difference across the diffuse part of the double layer (zeta potential).

Typically, the zeta potentials for latex or pigment particles are measured at different pH values. The zeta potential and hence the magnitude of the electric double-layer surface charge vary with the pH of the aqueous phase. The point at which the net charge is zero is termed the isoelectric point.

The stability of emulsion paints will be affected by the charge surrounding the latex pigment and extender particles. Flocculation will occur if the electric double layer is insufficient to maintain interparticle separation. Therefore, zeta potentials of the individual particles in the paint can give a measure of the tendency to flocculate and hence of the long-term stability of the paint. However, emulsion paints cannot rely solely on electrostatic stabilization because they need to withstand dilution with hard water. This means that some steric stabilization will invariably be used.

### Degree of Flocculation

Flocculation of pigment is more difficult to control in water-based coatings than in solvent-borne ones. Good pigment dispersion is important to achieve good gloss, opacity, and barrier properties.

The scattering efficiency of electromagnetic radiation by spherical particles is, among other factors, a function of their diameter and of the wavelength of the incident radiation. To give good opacity and whiteness,

**Figure 2** Particle size distribution for an acrylic latex by PCS.  $M_z$  is an expression of mean particle size that depends upon the scattering power per particle ( $P_i$ ) of size  $S_i$  where there are  $N_i$  particles of size  $S_i$ .  $M_z = \sum_i (S_i^3 P_i N_i) / \sum_i (P_i N_i)$

**Figure 3** Scanning electron micrographs showing pigment distribution in commercial solvent-based (A) and water-based (B) white gloss paints (bar = 1  $\mu\text{m}$ ).

the optimum diameter of  $\text{TiO}_2$  particles is 0.24  $\mu\text{m}$ , which gives maximum scattering of radiation at a wavelength of 0.55  $\mu\text{m}$ , the center of the visible spectrum. Flocculation of pigment means that the effective particle size of the  $\text{TiO}_2$  is increased and longer wavelengths of light will be preferentially scattered.

Pigment distribution in dried films can be observed directly by SEM. The surface of the film must first be etched away to reveal the pigment particles underneath (Figure 3). This can be achieved using a cold oxygen plasma generated by a commercial radiofrequency plasma barrel etcher. Image analyzers can be used to determine the dimension and area of the clumps of pigment.

The dependence of the scattered radiation on the degree of flocculation is the basis of instruments designed to measure flocculation. The Flocculation Monitor developed by Tioxide Europe Ltd measures the flocculation of pigment in wet and dry films. For

**Figure 4** Flocculation gradients for commercial solvent-based (solid symbols) and water-based (open symbols) white gloss paints.

dry films, samples of different thicknesses are irradiated with light of 2.5  $\mu\text{m}$  wavelength. The percentage of light that is back-scattered at each of the thicknesses is measured. A plot of reflectance versus film thickness produces a straight-line graph with a slope equal to the flocculation gradient. Low values indicate good pigment dispersion and high values indicate flocculation. This is illustrated in Figure 4 for commercial solvent-borne and water-borne glosses. The flocculation gradient for the water-borne system is 0.71 compared to 0.47 for the solvent-borne system.

For wet samples, a single value is obtained, and the lower the value the better the degree of dispersion.

### Standard Test Methods

There are a large number of standard test methods available for paints to ensure that specific performance criteria are met. The most widely used standards originate from the American Society for Testing and Materials (ASTM), British Standards Institution (BSI), Deutsche Institut für Normung (DIN), and the International Organization for Standardization (ISO). The methods used will depend on the paint type and intended application. A selection of methods is described below that are likely to be used for water-based coatings.

'Minimum film-forming temperature' is measured according to ASTM D2354. It entails the visual observation of cracking or whitening in films that have dried over a metal bar having a controlled temperature gradient. Temperatures between  $-5$  and  $90^\circ\text{C}$  can be covered with commercial equipment such as the Rhopoint MFFT-90.

At points on the bar above the MFFT, an applied latex will coalesce to produce a clear film if no pigment or other opaque materials are present.

Below the MFFT, a white, powdery, cracked film is obtained. Temperature sensors are placed at regular intervals under the bar and are used to control the temperature and to indicate the temperature at different points along the bar.

The gloss or 'sheen' (BS3900: Part D5) of a coating is determined on a meter that measures the proportion of light reflected at a fixed angle (normally 20°, 60°, or 85° depending on the gloss level).

'Opacity or contrast ratio' (BS3900: Part D4) is the paint's hiding power. It is determined by measuring percentage reflectance of light from films drawn down over black and white substrates. For equal hiding power over black and white, the contrast ratio is 100%.

'Porosity or water permeability' (ASTM D1653) is determined by measuring the rate at which water escapes from a cup sealed by a sample of the test coating. Alternatively, the cup can be filled with desiccant and the rate at which water migrates into the cup through the coating is measured.

A paint's 'stain resistance' is determined according to BS3900: Part G5 and entails applying typical stains to a coating and assessing the ease of removal using various cleaning solutions.

'Scrub resistance' is the ability of the paint to withstand repeated cleaning with detergent. Test methods such as ASTM D2486 require the use of mechanical scrub machines, brushes, or pads. Resistance can be quoted as weight loss for a given number of cycles or the number of cycles to erode a given film thickness.

'Blocking' is the undesirable sticking together of two painted surfaces when they are pressed together under normal conditions or under specified conditions of temperature, pressure, and relative humidity. The blocking point is the lowest temperature at which two coated surfaces in mutual contact will stick together sufficiently to injure the surfaces permanently and/or prevent easy separation. This test is important for coatings that could be applied to window frames.

There are several standard methods for determining block resistance (such as ISO 4622, ASTM 3003-71 and ASTM 4946-89). In ISO 4622 the pressure at which damage or sticking occurs to painted surfaces in contact at a given temperature and humidity is measured.

'Freeze-thaw stability' is determined according to ASTM D2243 by freezing the paint at -18 °C for 17 h then equilibrating at 23 °C and measuring any change in consistency on thawing.

'Leveling' of a paint describes the flow-out of brush marks, etc. It can be estimated by drawing the paint down with a crenellated applicator and

comparing undulations on the dry film surface with a set of standard photographs. The result is quoted on a scale of 1 to 10, where 1 signifies poor leveling.

'Surface dry time' (BS3900: Part C2) is estimated allowing a series of coated panels to dry and observing whether ballotini powder sticks to the coating at different time periods.

'Hard dry time' (BS3900: Part C3) is determined using a mechanical thumb that rotates a rubber pad in contact with the film under a specified force through 90° and looking for damage to the film. The film is hard dry when no damage can be seen.

'Salt spray resistance' is a common test applied to anticorrosive paints even though the validity of this test, especially for water-based coatings, has been questioned. BS3900: Part F4 describes a continuous spray method the result of which is a pass or fail. The coating is applied to a 4 inch by 6 inch (100 mm by 150 mm) steel plate and allowed to dry for 24 h. A scalpel is used to score a line through to the metal, starting 2.5 cm from the top of the panel to 2.5 cm from the bottom. The panel is then placed in a salt spray cabinet where it is subjected to a salt mist produced by spraying a salt solution through an atomizer. The panel is observed after 48 h, 1, 2, and 3 weeks and any blistering or adhesion problems are noted as well as the distance corrosion has extended from the cut.

'Fungal resistance' (BS3900: Part G6) is measured by inoculating the coating with a spray containing spores of several species of fungus. The test sample is then incubated for 14 days and the percentage coverage of the panel by fungal growth is estimated. The result is quoted on a scale of 0 to 5, where 5 is 70% coverage.

### Introduction

Paints are, in general, fluid materials that, applied as a thin film on a surface and after a drying or curing process, provide a solid, protective, decorative, or functional film.

From the first patent of a paint formulation filed by Averill Paint Co., New York, in 1867, and the initial production of a series of varnishes, dyes, and enamels in 1880 by Sherwin-Williams Co., the development of synthetic resins and the industrial production of a wide range of solvents and new pigments are the principal reasons for the tremendous development of the paint industry until today.

In spite of the development of environmentally friendly coating systems, based on the use of low-solvent content paints, free-solvent powder coatings, and waterborne-based products, many of the traditional organic solvent-based paints are difficult to replace without affecting the quality of the finished products.

In this article, a basic scheme for the complete analysis of organic solvent-based paints is described and the main analytical techniques available for this purpose are discussed.

### Chemical Composition

**Figure 1** summarizes the composition of paints. In general, a paint is composed of a binder, a pigment, and a solvent or mixture of solvents. However, some paints do not contain some of these products (e.g., varnishes do not contain pigments and solid paints do not include any solvent). Additionally, some additives are included in paint formulations during their manufacture in order to control the dispersion of the

different components or to facilitate the application or preservation of the paint.

### Binders

The binder is the most important component of a paint formulation. It binds the pigment particles in a homogeneous dispersion and fixes these particles to the painted surface, providing a final continuous film. Binders determine the application method, drying and hardening behavior, adhesion to the substrate, mechanical properties, and chemical and weathering resistance of the paints. The binder is dissolved in an appropriate solvent, and both binder and solvent constitute the vehicle of the paint.

Binders are, in general, organic resins (of natural or synthetic origin) but in some cases inorganic salts, for example, silicates, can be used as binders in fire-resistant paints.

Drying or curing of the paint film occurs by simple evaporation of the solvent in which the binder is dissolved (carried out at room temperature using air or accelerated by increasing the temperature), or by chemical reactions between the binder components (oxidation, addition, and condensation reactions have been employed in paint curing).

**Table 1** summarizes the different types of resins commonly employed in paint manufacture.

### Pigments and Extenders

Pigments are fine solid particles dispersed in the binder. Pigments provide color, gloss, and opacity required of the paint film. Some pigments also act as protective agents against corrosion by atmospheric agents.

On the basis of their chemical composition, pigments can be classified as inorganic (carbonates, oxides, sulfates, sulfides, silicates, chromates, molybdates, hexacyanoferrates, metals, and synthetic ceramic pigments) and organic (carbon black, aniline

### Introduction

Paints are, in general, fluid materials that, applied as a thin film on a surface and after a drying or curing process, provide a solid, protective, decorative, or functional film.

From the first patent of a paint formulation filed by Averill Paint Co., New York, in 1867, and the initial production of a series of varnishes, dyes, and enamels in 1880 by Sherwin-Williams Co., the development of synthetic resins and the industrial production of a wide range of solvents and new pigments are the principal reasons for the tremendous development of the paint industry until today.

In spite of the development of environmentally friendly coating systems, based on the use of low-solvent content paints, free-solvent powder coatings, and waterborne-based products, many of the traditional organic solvent-based paints are difficult to replace without affecting the quality of the finished products.

In this article, a basic scheme for the complete analysis of organic solvent-based paints is described and the main analytical techniques available for this purpose are discussed.

### Chemical Composition

**Figure 1** summarizes the composition of paints. In general, a paint is composed of a binder, a pigment, and a solvent or mixture of solvents. However, some paints do not contain some of these products (e.g., varnishes do not contain pigments and solid paints do not include any solvent). Additionally, some additives are included in paint formulations during their manufacture in order to control the dispersion of the

different components or to facilitate the application or preservation of the paint.

### Binders

The binder is the most important component of a paint formulation. It binds the pigment particles in a homogeneous dispersion and fixes these particles to the painted surface, providing a final continuous film. Binders determine the application method, drying and hardening behavior, adhesion to the substrate, mechanical properties, and chemical and weathering resistance of the paints. The binder is dissolved in an appropriate solvent, and both binder and solvent constitute the vehicle of the paint.

Binders are, in general, organic resins (of natural or synthetic origin) but in some cases inorganic salts, for example, silicates, can be used as binders in fire-resistant paints.

Drying or curing of the paint film occurs by simple evaporation of the solvent in which the binder is dissolved (carried out at room temperature using air or accelerated by increasing the temperature), or by chemical reactions between the binder components (oxidation, addition, and condensation reactions have been employed in paint curing).

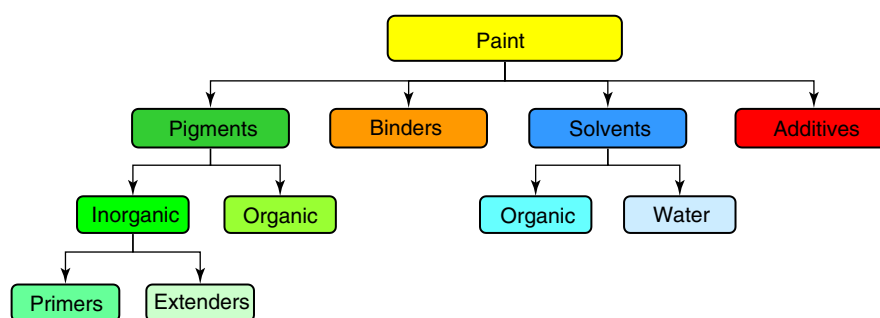

**Table 1** summarizes the different types of resins commonly employed in paint manufacture.

### Pigments and Extenders

Pigments are fine solid particles dispersed in the binder. Pigments provide color, gloss, and opacity required of the paint film. Some pigments also act as protective agents against corrosion by atmospheric agents.

On the basis of their chemical composition, pigments can be classified as inorganic (carbonates, oxides, sulfates, sulfides, silicates, chromates, molybdates, hexacyanoferrates, metals, and synthetic ceramic pigments) and organic (carbon black, aniline

**Figure 1** Main components of liquid paint formulations.

**Table 1** Synthetic resins commonly employed in paint manufacture

Resin type	Description
Alkyd	Condensation products of polybasic acids or anhydrides and polyhydric alcohols. Contains monobasic fatty acids
Polyester	Condensation products composed mainly of co-reacted di- or polyhydric alcohols and di- or tribasic acids or anhydrides
Polyurethane	Condensation products of diisocyanate and diol
Phenolic	Condensation products of phenol and formaldehyde
Epoxy	Polyesters based on the reactivity of the epoxy group (i.e., condensation product of bisphenol A and epichlorohydrin)
Polystyrene	Co-polymer based on styrene monomer
Acrylic	Co-polymers based on multifunctional monomers, such acrylates and methacrylates
Vinyl	Contains unsaturated vinyl groups
Amino	Condensation products of an amide and formaldehyde
Silicone	Produced by intermolecular condensation of silanols
Cellulosic	Polymer based on cellulose
Fluorocarbons	Co-polymer of fluorocarbon monomers

black, phthalocyanines, monoazo compounds, azo dyes and vat dyes, quinacridones, and other substances such as metal complexes and basic dyestuff complexes).

Organic pigments have more intense colors and are more brilliant than inorganic ones. However, the latter provide higher opacity and hiding power.

In addition to pigments a series of extenders or charges are introduced in the paint manufacturing process. Extenders have a poor hiding power and are more economical than pigments, and these products can be used as fillers to introduce modifications in the final characteristics of the paint, such as to modify the thixotropic behavior of the matrix or to reduce

the cost of the paint. The extenders most usually employed are carbonates, sulfates, silicates, phosphates, borates, silica, and alumina.

### Solvents

Solvents are introduced into the paint formulation to dissolve the binder and to provide adequate fluidity of the paint to allow it to be applied. The most important characteristics of solvents are their capacity to dissolve the resins and their volatility, which controls the speed of evaporation. Solvents employed in solvent-based products are hydrocarbons (both aliphatic and aromatic compounds), oxygenated solvents (frequently alcohols, esters, ethers, or ketones), and terpenic solvents; in general, mixtures of solvents are used in paint manufacture.

The present trend in paint manufacture is to avoid high concentrations of low-boiling solvents in order to prevent the emission of pollutants into the environment. However, the worldwide production of solvent-based paints for industrial purposes continues to be very important.

### Additives

Additives are minor components in the paint composition and, in general, each one of these products represents no more than 2% of the total volume of the formulation. However, they are important in order to achieve specific properties of the paint.

The most frequently used paint additives are wetting, dispersant, and antissettling agents, used to prevent pigment settling; antiskinning agents, employed to prevent surface drying; defoamers and antifoams, necessary in the manufacture of aqueous and some solvent-based paints; driers; preservatives and fungicides, employed to prevent growth of microorganisms; thickening agents to control the rheological properties; ultraviolet absorbers, which reduce the degradation of the coating by sunlight;

catalysts, employed for the curing of paints; anti-floating and antiflooding agents; and matting agents. Paint additives can be classified into two groups as a function of their solubility or insolubility in the paint vehicle; accordingly, in paint analysis they can be found in the pigment or in the binder fraction after treatment of the sample with an appropriate solvent.

## Production of Paints

The manufacture of paints is based on adequate dispersion of the pigment into the vehicle. The dispersion of the pigment is carried out by mechanical stirring and by means of a series of additives (humidifiers, surfactants, antifoaming products), after which the mixture is ground or milled, using ball mills, to achieve adequate fineness of the dispersion. After this process the physical parameters, such as color and viscosity, are adjusted to obtain the desired properties. Filtering, filling, and shipping are the final steps in paint manufacture.

The most important characteristics of paint are determined by the amount of pigment and binder, and so an important parameter, which can be used to evaluate paint films, is the volume of pigment and charges, termed the pigment volume concentration (PVC). This can be defined as

$$\text{PVC}(\%) = \left( \frac{\text{volume of pigments and extenders}}{\text{volume of nonvolatile components}} \right) \times 100$$

The properties of paints, such as water permeability, corrosion resistance, gloss, hiding power, or the tendency to blister, are dependent on the PVC. There is a critical value of this parameter, called the critical pigment value concentration, at which the practical properties of the paint undergo important changes.

The PVC of a paint varies as a function of its use as a primer (in this case values of PVC between 30% and 50% are recommended), as an intermediate film (a PVC between 30% and 35% is most appropriate), or as a finishing paint (in which case the PVC must be lower than 20%). Only in the case of paints with a high content of zinc is PVC higher than 95% expected.

## Analysis of Paints

In the paint manufacturing industry, chemical analysis is essential for investigating and developing new products, solving problems during the production process, and controlling the quality of both the raw materials and the final products. The analysis of the

manufactured products can provide valuable information for the technical development of other industries and can help to solve customer complaints.

The analysis of a liquid paint can be performed on a well-characterized sample, during its production, or on a finished unknown sample. In the first case it is possible to develop simple and rapid analytical procedures in order to control various parameters.

The analysis of unknown samples is the most difficult problem because of the lack of prior information that must be compensated by the development of a rigorous analytical scheme. So it is necessary to carry out a series of pretreatments of the sample in order to simplify the application of instrumental techniques to the identification and quantitative analysis of the components. In this case, prior separation of the paint components is one of the most important steps.

On the other hand, a series of technical norms have been developed to guarantee the quality and characteristics and/or properties of paints and coating materials; these are provided by international organizations such as the ASTM (American Society for Testing and Materials) and ISO (International Standard Organization). Concerning the control tests that are currently applied to paint samples, **Table 2** summarizes the most important properties of paints and the techniques employed in their evaluation.

When paints are exposed outdoors they generally become less glossy and have more tendency toward cracking and flaking, also showing color changes or fading. Paints that are indoors and exposed to sunlight that has passed through window glass generally degrade less rapidly as they are not exposed to rainfall or to the ultraviolet (UV) radiation from the sun. Permanence or fastness refers to the chemical stability of the paint pigments in relation to any chemical or environmental factor, including light, heat, water, acids, alkalis, or mold.

Different standard test methods have been proposed in order to evaluate lightfastness and weather fastness of paints. A painted test panel, generally with controlled conditions of temperature and humidity, is exposed to a light source (sun, artificial daylight fluorescent lamp, or xenon arc) directly or behind glass. After a specified period of exposure, any change in color in the paint film is determined by comparing the sample with a reference specimen that has been stored away from the light. Color difference units can be calculated by the CIE 1976  $L^*a^*b$  color difference equation and according to the relative resistance to change paint pigments can be assigned to categories of relative lightfastness. ASTM defines a five-point rating system for paints lightfastness, from I (excellent) to V (very poor).

**Table 2** Test employed for the study and control of the properties of liquid-solvent based paints

Property	Assay
Viscosity	Standardized flow cups for Newtonian fluids Brookfield viscometer for non-Newtonian materials
Density	Measurement using a pycnometer
Degree of fineness of dispersion	Using a fineness gauge
Opacity or hiding power	For liquid film using cryptometer  By measurement of the reflectivity of a dry film applied on a black-and-white hiding-power chart
Gloss	Using a reflectometer by measurement of the specular reflectance for different angles of incidence
Flash point	Measurement of the lowest temperature at which the application of a test flame ignites the vapor generated by the heated sample
Volatile content	
Nonvolatile matter	By difference of weight after heating the sample at 105°C in an oven for ~3 h
Pigment content	By weight difference after extraction of all the vehicle using a suitable solvent mixture and centrifugation By low-temperature furnace ashing (some organic pigments may be lost by this method)
Color measurement	By measuring the spectral reflection using a spectrophotometer and establishing the color coordinates

Another lightfastness category is the Blue Wool Scale, which includes eight levels: from 1 (poor) to 8 (extremely lightfast).

### Sampling of Paints

Sampling of paints can be carried out during manufacture, in the filling step, or from a finished consignment. In the first case, the sample must be previously homogenized, or several samples must be taken at different levels using an adequate probe. In this case, it is necessary to carry out a filtration step before the analysis.

When the sampling is carried out during filling, the laboratory sample is obtained from different samples taken at regular intervals, but when the paint is already filled it is necessary to carry out random sampling of a representative sample comprising  $\sqrt{n/2}$  packages,  $n$  being the total number of packages in the lot. Adequate sample containers must be selected to avoid losses of volatile solvents through their walls.

In general, it is necessary to ensure that the laboratory sample is representative of the whole consignment.

To weigh liquid paint sample it is convenient to use a glass syringe and to determine the mass of the sample by difference. This process avoids losses of volatile compounds during sample handling.

In the analysis of coatings of dry paint film, the components can be characterized using microscopic techniques that can be applied to the study of the homogeneity of samples and require only small amounts of material.

### Separation of the Paint Components

A prior separation of the binder, pigments, and solvents from the whole paint is recommended for their complete analysis by the different techniques available.

The separation of the pigment from the vehicle is carried out by centrifugation of the sample. For this purpose an adequate quantity of paint (of the order of 20 ml) is placed in a centrifuge at 5000 rpm (or up to 20 000 rpm for samples containing finely divided pigments and low-density and viscous solvents) for 30 min or until complete separation is achieved. To avoid sedimentation of the pigment dragging significant quantities of the ligand, especially with high-viscosity samples, it is recommended to dilute the sample with an appropriate solvent, such as tetrahydrofuran or methyl ethyl ketone. Samples are decanted to separate the vehicle and the pigment is washed several times with the diluent employed.

When it is necessary to determine quantitatively the amount of pigment in a paint sample, an accurate weight of sample is extracted and re-centrifuged thrice with a solvent (a toluene–acetone, 2:1 v:v, mixture or tetrahydrofuran), and after a final extraction with ethyl ether or petroleum ether, the pigment is dried in an oven at 105°C for 2 h and its amount established by weighing.

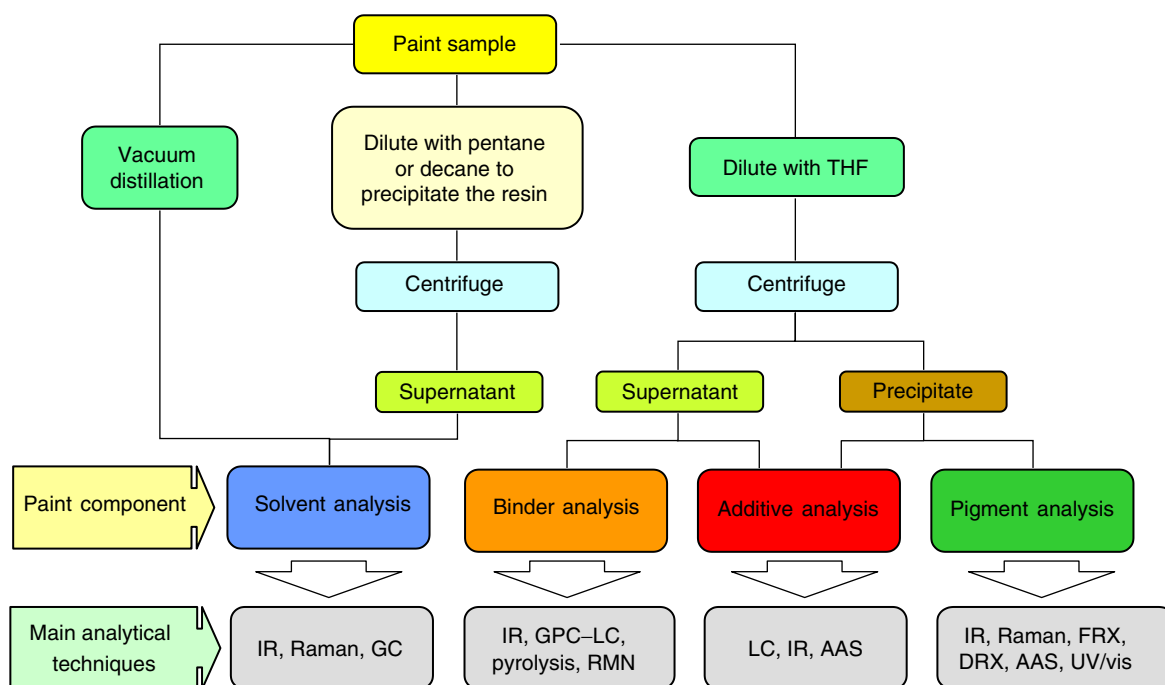

The evaporation of the solvent, added to the vehicle for the separation of the pigment by centrifugation, permits isolation of the binder for subsequent identification.

The separation of the solvent from the other components of a paint sample can be carried out by vacuum distillation. For this purpose tricresyl phosphate is added to the sample and the mixture is heated (at 155°C or 160°C) in a silicone bath under vacuum.

Figure 2 summarizes the procedures employed in the separation of solvent-based paint components.

### Analytical Techniques Employed in Paint Analysis

At present, the majority of procedures employed for the identification and quantification of paint

**Figure 2** Separation scheme for solvent-based paint components and analytical techniques employed for their analysis.

components are based on the use of instrumental techniques. However, some chemical methods can be applied to determine the presence of cations, anions, or functional groups in a paint sample and from these results information about pigments and binders can be obtained. The elemental analysis of paint, after classical fusion with sodium, permits the establishment of the presence of nitrogen, sulfur, halogens, or phosphorus, and from that it information about the type of resin that constitutes the binder can be obtained.

The use of selected volumetric methods permits quantitative determination of some functional groups such as carboxylic acid, hydroxyl or isocyanate groups by means of acid–base titrimetric, saponification, or condensation reactions. From these data the content of polymer in the binder can be established.

Among techniques employed in paint analysis, spectrophotometric methods (infrared (IR), Raman, and UV–visible), chromatography (both gas and liquid), X-ray diffraction and fluorescence, atomic spectrometry, nuclear magnetic resonance, and pyrolysis are the most useful and provide more selective or more sensitive information than the classical procedures about the main components of paints. In the following sections the main merits and applications of these techniques will be described.

**Infrared spectroscopy** IR spectroscopy provides the most valuable information on the qualitative composition of paints. Binders, pigments, solvents, and some additives can be characterized by their corresponding IR spectra. However, the identification of components can be facilitated if the IR spectra are obtained after separation.

For the characterization of the binder, several drops of the vehicle, previously separated from the pigment, can be dried on the surface of an appropriate crystal and the corresponding spectrum recorded. From the presence or absence of typical bands of the different functional groups in this spectrum, the type of resin employed can be identified. From the IR spectra it is also possible to analyze quantitatively mixtures of resins, such as those of the polyester and epoxy type.

To obtain the IR spectrum, the pigment can be prepared as a potassium bromide pellet using small amount of pigments previously separated by centrifugation. **Figure 3** shows the IR spectra of organic and inorganic pigments compared with an extender. In the case of organic pigments a well-defined spectrum can be seen that provides much information; for inorganic pigments only a small number of bands are found. Inorganic pigments with polynuclear anions present very similar spectra in spite of the presence of different cations. However, IR spectrometry can be used for the quantification of several

**Figure 3** FTIR spectra of pigments and charges in potassium bromide pellets: (A) organic pigment (copper phthalocyanine type  $\beta$ ); (B) inorganic pigment (titanium dioxide); and (C) charge (calcite).

inorganic charges such as barium sulfate, calcium carbonate, and talc, with the use of a suitable internal standard.

Solvents employed in paint manufacture can be qualitatively and quantitatively determined using liquid cells or from the spectra obtained from a few drops of the solvent, previously distilled, deposited between two crystals of an alkyl halide (in this case, for quantitative purposes an internal standard or the bands quotient approach must be employed). From these spectra the presence of several solvents in the formulation can be established and, if the mixture is not too complex, quantitative determination of all solvents can be carried out without chromatographic separation. Attenuated total reflectance (ATR) measurements offer a simple and fast alternative to the use of transmittance cells for qualitative and quantitative analysis. For this purpose, the solvent fraction obtained from the paint is placed over the surface of an ATR crystal (usually ZnSe). **Figure 4** shows the spectra obtained for pure solvents and the solvent fraction of one polyester type paint.

**Raman spectroscopy** Raman spectroscopy offers information complementary to that obtained by IR spectroscopy. Problems related to sample fluorescence and poor sensitivity are the main drawbacks, but Raman spectroscopy requires a minimum

**Figure 4** FTIR spectra of pure solvents and a typical solvent mixture for polyester-type paint. Measurement mode: attenuated total reflectance.

**Figure 5** FT-Raman spectra of a whole solvent paint and different components.

manipulation of samples and the spectra can be obtained directly from liquid paint samples contained in glass vials or using remote optical fibers.

The use of near-FT-Raman spectrometers, usually with a YAG laser ( $\lambda$  excitation of 1064 nm), reduces fluorescence enhances signal-to-noise ratio as compared with dispersive spectrometers by increasing the number of cumulated scans per sample. **Figure 5** shows the FT-Raman spectra of a paint sample and different components, all directly obtained in the back-scattering mode.

**Chromatographic methods** Gas chromatography (GC) is the most useful technique for quantitative analysis of solvent mixtures in paint samples. The solvent, after isolation from the other components of the paint, is injected directly into the chromatograph.

Either capillary or packed columns can be used. However, when samples contain naphtha solvent (a complex mixture of hydrocarbons) the use of capillary columns is required to obtain adequate separation of all the solvents.

Headspace GC permits direct analysis of paint samples without prior separation, providing a rapid

**Figure 6** Headspace gas chromatogram obtained from a solvent-based paint. Instrumental conditions: fused-silica column (0.20 mm ID, 50 m length) with Carbowax 20 M stationary phase; carrier gas helium (at  $0.6 \text{ ml min}^{-1}$ ); FID detector.

method for quantitative analysis of solvent (see **Figure 6**).

Detection systems usually employed in GC for the analysis of solvents in paints are the flame ionization detector (FID) and the electron-capture detector, but coupled GC and Fourier transform infrared spectroscopy (FTIR) or GC with mass spectrometry (GC-MS) offer improved peak identification capability.

Liquid chromatography (LC) can effectively replace GC in the analysis of paint components with low volatility. Among LC techniques the most interesting in paint analysis is gel permeation chromatography (GPC), which provides an interesting tool for the characterization of binders from the study of the composition and molecular mass distribution of the resins.

The analysis of binders by GPC requires the prior isolation of the binders and their dissolution in an appropriate solvent (tetrahydrofuran is one of the most frequently used). The separation of different oligomers of the resins takes place in a series of columns arranged in increasing order of porosity. A refractometer is commonly used as the detection system. FTIR can be used as a selective detector but it has some limitations due to the nature of the mobile phase employed. Open columns can be used for the GPC analysis of polymers with a high molecular

mass, but for low molecular mass polymers open columns do not provide sufficient resolution and high-performance GPC is absolutely necessary. Typical gel permeation chromatograms of polyester and an epoxy resin are shown in Figure 7.

Thin-layer chromatography can also be applied to the separation and qualitative characterization of organic pigments, but meager information is provided by this technique compared with spectrometric techniques and GC or LC.

**Pyrolysis** Pyrolysis is really a sample preparation technique and not an analytical technique. However, the interest in pyrolysis for the characterization of polymeric materials justifies some comments.

Pyrolysis is based on the rapid heating of the sample under controlled conditions and online identification of the decomposition products. GC, FTIR, and MS are used for the analysis of the pyrolyzed samples.

For the determination of binders by pyrolysis a small amount of sample, prepared by removing the pigment by centrifugation and evaporating the solvent, is introduced into a pyrolysis chamber, in which it is heated under a carrier gas flow. Volatile products obtained from pyrolysis are introduced

into a gas chromatograph to separate and identify them. Polymers with well-characterized composition are used to compare the chromatogram of the sample with the different types of resins employed as binders.

This procedure provides poor reproducibility, because the pyrolysis products depend strongly on the experimental conditions, but provides a useful analytical tool in the identification of acrylic and vinylic polymers or monomer units from polyester, polyurethane, and phenolic and polyacrylate resins.

#### X-ray fluorescence and X-ray diffraction techniques

X-ray fluorescence (XRF) spectroscopy is useful for qualitative elemental analysis of paint samples. It does not require dissolution of the sample and can be applied to dry films. When an energy-dispersive instrument is employed, XRF provides rapid information on the presence of elements of atomic number higher than or equal to 12 (e.g., above magnesium). However, from a quantitative point of view, the sensitivity, accuracy, and reproducibility of XRF measurements is lower than that of flame, electrothermal, or plasma atomic spectrometry.

Figure 8 shows the XRF spectra of different solvent-based paints obtained as dry films.

X-ray diffraction is a powerful technique for discriminating inorganic pigments and extenders some specific applications are very interesting in the field of paints. Sample preparation is simple and the compounds can be identified directly and not indirectly through their elements.

**Atomic spectrometry** The use of modern analytical techniques based on atomic absorption and emission spectrometry provides accurate and precise quantitative determination of inorganic species in paints.

Atomic absorption spectrometry (both using flame and electrothermal atomization) and plasma emission spectrometry, especially inductively coupled plasma-atomic emission spectrometry (ICP-AES) provide selective methods for quantification of inorganic species at different concentrations. These techniques are important for the analysis of inorganic pigments, charges (especially inorganic extenders), and additives such as catalysts, driers, and antifouling compounds.

Atomic spectrometry generally requires prior dissolution of the sample, which can be carried out with either acids or organics solvents, but in some cases necessitates destroying the matrix by means of a wet acid treatment or a dry digestion. This can be a serious drawback, but the new strategies for sample preparation, based on the use of microwave-assisted digestion procedures for sample dissolution and

**Figure 7** Liquid gel permeation chromatogram of polyester and epoxy resins. Columns: Waters Ultrastayage  $10^4$  Å, 500 Å, and 100 Å. Solvent carrier: tetrahydrofuran at  $1 \text{ ml min}^{-1}$ . Oven temperature:  $36^\circ\text{C}$ . Detector: differential refractometer.

direct introduction of solid samples as slurries or emulsions, can reduce problems involved in sample preparation.

**Nuclear magnetic resonance spectroscopy**  $^1\text{H}$  and  $^{13}\text{C}$  nuclear magnetic resonance (NMR) are effective for the characterization of resins in the binders of paints.

Binders for NMR analysis must be isolated from the sample and dissolved in deuterated chloroform (a very good solvent for many resins as it produces only small proton impurity peaks and is less expensive than other deuterated solvents). The NMR spectra of binders provide information about the functional groups present.

Using flow charts for paints the type of resin employed can be identified, and in some cases, for example, alkyl and phenolic resins, quantitative determination of resins can be made from the relative areas of the spectrum peaks.

$^{13}\text{C}$  NMR provides better results than  $^1\text{H}$  NMR for the resolution of peaks obtained from high molecular mass and very viscous polymers, but the instrumentation required is more expensive and a larger amount of sample and longer analysis times are involved.

**UV-visible spectrophotometry** UV-visible spectrophotometry can be employed for identification of pigments, especially for the characterization of organic compounds or the determination of light

filters. The technique is based on the possibilities offered by an appropriate combination of solvent extraction or the selective solubility of each pigment and its characteristic absorbance spectra. The use of mathematical procedures for the deconvolution of spectra and the use of derivatives can improve the selectivity of these determinations.

### Recent Developments for Quality Control of Paints

Quality assurance in the paint industry demands not only quality control of final products, but also a careful control of raw materials and manufacturing processes. Paint manufacturers require simple and fast analytical procedures for online control. It is important to obtain measurements directly from whole samples, without any prior treatment, and the incorporation of sample preparation techniques, such as supercritical fluid extraction or accelerated solvent extraction, which facilitate the separation of paint components prior to their analysis.

For process control, analytical techniques such as vibrational spectroscopies, which provide information about paint composition, are important based on: (1) the popularization of FT instruments, with a better signal-to-noise ratio and fast data acquisition speed; (2) reflectance techniques (total attenuated and diffuse), photoacoustic spectroscopy, and the development of optical fiber-based devices that provide easy spectrometric measurements on crude samples; (3) vapor-phase generation coupled with FTIR for fast analysis of the volatile paint fractions;

and (4) the improvement of database and library tools.

Finally, it is necessary to mark the importance of chemometrics for the exploitation of instrumental data from paint samples. From the treatment of vibrational spectra (near-IR, IR, and Raman) or chromatographic signals and using calibration models, established from well-known paint samples, chemometrics provides a powerful tool for the prediction and control of the properties of paints throughout their manufacturing.

## Introduction

Determining particle size distributions are one of the key elements in ensuring product performance and consistency. The range of materials and processes for which particle size distributions are important is vast. Many materials cross national boundaries and thus it is necessary to declare protocols of measurement in order to avoid unnecessary disputes.

A range of ISO standards (see Appendix A) to ensure international agreement are being created.

The materials range in size from nanometers to millimeters and many techniques have been invented to perform the particle size measurement.

The more commonly encountered methods will be described in this section. The modern equipments available for particle size measurements rely upon sophisticated software. However, it should be remembered that most of these do not measure particle size directly but rely upon the interpretation of some other parameter.

How this interpretation is conducted together with any attendant assumptions bears considerably upon the final result. With this in mind each measurement method covered will contain a description of the operational method.

Crushed road stone and gravels are made available in millimeter size fractions created by screening. Sands for building and sands for molds used in metal casting foundries are in the fractions of a millimeter range. Portland cement is ground to achieve a broad range of sizes from submicrometer to  $\sim 200\ \mu\text{m}$ . This is to ensure a fairly rapid onset of gelling whilst maintaining a desirable 28-day strength.

Powdered drugs suitable for the treatment of asthma are 'micronized' to 2–3  $\mu\text{m}$ . Much finer particles would be exhaled and thus wasted whilst much larger particles would remain in the bronchial tubes and not reach the deep lung where the drug is most effective.

Particles destined for use in sun-block creams are created to have a size of 70–80 nm.

Studies of proteins require sizing instruments capable of measuring down to a few nanometers.

Agricultural sprays are required to be atomized within size limits. Very large droplets are wasteful of the chemical, whilst very fine droplets can be carried away by the wind and cause damage or destruction of neighboring crops.

The fuel efficiency and emission levels of diesel and petrol engines are intimately dependant upon fuel atomization.

Products are also supplied in the form of emulsions, e.g., paints, adhesives, bitumens, and some medicines whilst others are created as suspensions, e.g., casting slips and coal slurries for burning in electricity power plants.

## Particle Size Distributions

Particle sizing presents a challenge in as much it attempts to provide a single value of size for what are usually three-dimensional objects. The sphere is the only shape for which the single value of diameter fully characterizes its size.

The quantity of particles that have a specific size is also required (Figure 1).

A person with a headache who takes an analgesic medicine in powdered form receives a defined volume or weight of the drug. The powder is likely to have a distribution of sizes. The rate of dissolution

will be greatly influenced by volume of drug that has the finer sizes due to the larger surface area presented by these sizes. For dissolution studies a quantity axis in terms of surface area against size is important.

In polishing a surface, one or two rogue particles in the polishing material can ruin the whole process with scratches. The number of objects having the size of the grit is important here.

Instruments and techniques providing particle size distributions have different value judgments in terms of both the particle size reported and in terms of the quantity axis.

Instruments and techniques will only provide common estimates for these values in the case of homogeneous spheres having defined physical properties.

Therefore, any published particle size distribution should also contain a full description of the method of preparation of the material and the method by which the size distribution was determined.

The ISO standards (Appendix A) not only define methods of validation of the units described but also provide excellent advice on their general use and on the preparation of the material to be measured.

The relationship between the number of particles that have a specific size and the equivalent volume is proportional to the inverse of the particle diameter, cubed ( $1/D^3$ ). Therefore, if knowledge of the particle size distribution by number is required, a technique that examines each particle is chosen and the value added to a specific size class.

If a size distribution by volume is required, a technique that responds principally to the volume of material that has a specific size is chosen.

Attempts to numerically transform from number to volume or vice versa are to be discouraged for any size distribution whose dynamic range of sizes exceeds 8:1.

**Figure 1** A typical particle size distribution. The quantity axis is by volume.

Modern particle size instruments have been designed to be easy to use. However, considerable additional skills and understanding is required before reliable results can be obtained. These skills include subsampling and dispersion of aggregates. The understanding of how to transport all the sizes of particles to the measurement zone without introducing bias and the avoidance of introducing additional, unwanted, artifacts such as dirt and air bubbles is also needed.

## Particle Size Instruments

Table 1 provides a brief synopsis of the instruments and their properties that are in more common use.

Both image analysis and electrical zone sensing observe and respond to each particle. Laser diffraction, sedimentation, and dynamic light scattering data are obtained from ensembles of dispersed particles in suspension.

## Laser Diffraction

Introduced in the late 1970s, laser diffraction is now the most widely accepted method of general-purpose particle sizing. The technique has wide application, is nonintrusive, easy to use, and does not require calibration.

The ISO standard ISO 13320-1, Particle size analysis – Laser diffraction methods – Part 1: General principles, covers this method.

Particle sizing from 0.05 to 2000  $\mu\text{m}$  is available within a single instrument, in most modern implementations, for liquid suspensions of particles, dry powders, and droplet sprays. Robust versions of the technology are now to be found online in hostile environments, typical of which is the manufacture of cement.

## Theory

A dilute suspension of particles or droplets is caused to flow through a measurement zone (see Figure 2).

**Table 1** Principal features of particle sizing instruments in common use

	<i>Laser diffraction</i>	<i>Dynamic light scattering</i>	<i>Sedimentation</i>	<i>Electrozone sensing</i>	<i>Image analysis</i>	<i>Sieving</i>
Size range ( $\mu\text{m}$ )	0.05–2000	0.01–3, limited by density	0.1–100	0.2–200	Visible, 0.5–500; electron, 0.01–10	10 $\mu\text{m}$ to several millimeters
Dynamic range	1000:1	10:1	20:1	40:1	10:1 per image	100:1
Principal reported quantity	Volume	Intensity weighted distribution	Mass	Number and summed volume	Number	Mass
Property measured	Angular light scattering	Light intensity fluctuations	Settling speed	Electrical pulse	Image size	Mass
Time required for one completed measurement	1–2 min	5–10 min	6–60 min, depending upon size range	10–15 min	10–30 min	Dry 10–30 min; wet 1–2 h
Resolution	Medium to high	Low	Medium	High	High	Medium
Calibration required	No	No	No	Yes	Yes	No
Validation method	Certified reference materials	Certified reference materials	Certified reference materials	Certified reference materials	Certified reticle	Optical verification of mesh size
Suspension media	Liquids or gases	Liquids	Liquids	Liquids	Particles deposited on a substrate	Air or liquid
Dry powder measurement	Yes	No	No	No	Yes	Yes
Droplet sprays	Yes	No	No	No	Possible	No
Concentration	Volume fraction <0.01, limited by multiple scattering	Very dilute	Upper volume fraction limited to avoid hindered settling	Dilute to avoid coincidence	Limited number per slide	Several grams of sample required
Density limitations	None	Upper size density limit that induces sedimentation	Upper size density limit when settling induces turbulence	Limited	None	None

A laser beam is passed through the measurement cell and brought to a waist of focus at the plane of the multielement detector. This is the reverse Fourier optical setup. Conventional Fourier optics arrangements are also used.

It is required that measurements of the angular dependence of scattering be conducted over as large a range of angles as possible. The laser beam may be polarized facilitating measurements of the polarization dependence of the scattered light.

The extinction or obscuration due to the presence of the particles is additionally measured. Finally, the scattering dependence with wavelength can be established using additional wavelength sources.

Gustav Mie formulated a rigorous solution, predicting the scattering from a homogeneous spherical particle, by solving Maxwell's equation. With the advent of modern PCs, Mie theory is the preferred model for predicting how particles scatter light. Knowledge of the refractive index of the particles, both real and imaginary, together with the refractive index of the suspending medium enables a matrix predicting the anticipated signals from each detector

for all size classes to be precalculated and stored in memory.

A typical energy response from latex beads in water is shown in Figure 3.

We can see from Figure 3 that large particles scatter light at small angles and small particles scatter light to greater angles. We also note that strong amplitude dependence is evident below  $\sim 10\ \mu\text{m}$ .

Below  $\sim 0.3\ \mu\text{m}$  additional data in the form of information on wavelength, polarization, and extinction dependence is needed.

The approximation of Fraunhofer has been employed in some implementations. However, it does not include amplitude and polarization dependence and also ignores light transmitted through the particle. Thus, the Fraunhofer approximation is prone to predicting incorrect quantities of small particles having a specific size. A matrix of the predicted light scattering data is precalculated and stored in memory.

The ensemble of scattering from the sample presented in the measurement cell is sampled many times to form a stable average of the light contribution to each detector.

A direct matrix inversion, with a constraint to obtain a particle size distribution, is adopted in some implementations. Other solutions to the inversion problem are achieved by iteration of the particle size distribution until a 'best fit' between observation and prediction light energy is achieved. This necessary constraint limits the resolution.

Designers of laser diffraction units strive to achieve a design that results in the predicted energy matrix being optimal and consistent with the light energy contribution from the presence of each size class.

Suspension concentrations are produced such as to ensure single scattering conditions. Some progress has been made in order to accommodate the influence of multiple scattering.

**Figure 2** An example of the arrangement of components in a laser diffraction unit.

**Figure 3** Light energy predicted over  $140^\circ$  of log-spaced angle. Plotted with log-spaced size range  $0.1\text{--}2000\ \mu\text{m}$ . The vertical axis represents the energy recorded by an idealized detector.

## Applications

Almost any form of finely divided powder, droplet, or emulsion can be measured using laser diffraction. This in turn leads to the technique having penetrated into almost every branch of industry.

Applications include the following material systems: powdered materials either dry or in suspensions; continuous or pulsed droplet sprays, emulsions, and some solids in solids provided that the suspending medium is transparent.

## Photon Correlation Spectroscopy (Submicrometer Particle Sizing)

### Introduction

As in so many other fields, advances in measurement, in this case submicrometer particle sizing using laser light scattering, only became a reality when suitable technology became available to exploit the basic theories and mathematics that were already available.

By 1968, the laser was an established light source as was single photon detection with the photomultiplier tube.

The digital correlator for processing single photon detection from a photomultiplier tube proved invaluable in retrieving useful information from the very weak scattering encountered with very dilute systems of nanometer-sized particles.

The International Standard ISO 13321:1996 'Particle size analysis – Photon correlation spectroscopy (PCS)', provides for methods of validation as well as good general advice on the use of this method. This standard is being amended to include frequency analysis techniques as well as addressing measurements at concentrations greater than very dilute.

### Theory

Consider a dilute suspension of nanometer size molecules or particles illuminated by a monochromatic coherent light source of defined wavelength. Provided the particles have a refractive index that is different from the suspending medium light scattering will be observed.  $K_s$  is the modulus of the scattering vector,  $n$  the refractive index of the medium,  $\lambda$  the wavelength of illumination, and  $\theta$  the angle of observation.

The wavelength of the scattered light from each particle is identical to the incident beam and its phase

is initially coincident with that of the incident beam. The amplitude of the light scattered by each particle depends upon its scattering cross-section and the difference in refractive index from that of the suspending medium. If the particle size is much less than the wavelength, the scattering is assumed to emanate from a point source (i.e., isotropic radiation).

If the viewing screen is placed some distance from the measurement cell and positioned at a small angle from the incident beam, a speckle pattern will be observed due to the interference pattern created from the scattering of the ensemble of particles within the measurement cell.

The size of each speckle is determined by the wavelength, observation angle, and the geometry of the incident beam. The aperture of any single photon detector should ideally be equal to the size of a single speckle. This is defined as coherent detection; that is, particles will be moving (diffusing) under the influence of Brownian motion. This means that the speckle pattern is moving about upon the screen at a rate determined by the rate of particle diffusion, the wavelength of illumination, and the angle of observation.

The output of the coherent detector, positioned in the plane of the screen, will now take the form of a fluctuating intensity with respect to time.

The output of the single photon detection system electronics may be such as to form equal height, equal width pulses for each photon detected, whose output rate is high for high-intensity illumination and low at low-light levels. This form of signal is an ideal input for the digital autocorrelation process.

Within the Physics group of RSRE (now QinetiQ), in Malvern, Worcestershire, England, Dr Roy Pike, FRS, and his team created a Digital Correlator to process the photon output of the photomultiplier such that submicrometer particle sizing, using a laser, became a reality.

The autocorrelation function has the form of

$$G_2(\tau) = [I(t) \cdot I(t + \tau)]$$

The square brackets refer to an average value of the product  $I(t) \cdot I(t + \tau)$  where  $\tau$  is a time difference independent of the arbitrary time  $t$ .

For the case of a large number of monosized-dispersed particles in the measurement cell,  $G_2(\tau)$  has the form of a single exponential decaying function of time difference  $\tau$ .

$$G_2(\tau) = A[1 + B \exp(-2\Gamma\tau)]$$

The decay constant  $\Gamma$  relates to the rate of the translational diffusion coefficient  $D$

$$\Gamma = DK_s^2$$

The diffusion coefficient of noninteracting spherical particles of diameter  $x$  is provided by the

Stokes–Einstein relationship:

$$D = \frac{kT}{3\pi\eta x}$$

where  $k$  is Boltzmann's constant,  $T$  the absolute temperature, and  $\eta$  the viscosity of the medium.

Early designs of correlator were built having linear time difference  $\tau$ . However, it was demonstrated that it was better to provide logarithmically spaced time intervals, as this offered the optimum information for subsequent data analysis.

A process of normalization of the measured autocorrelation function is applied. Monitor channels of the input count and total number of samples taken provide the data for the normalization process.

A further refinement, referred to as symmetrical normalization, is beneficially applied.

In practice, samples presented for measurement will have a distribution of sizes.

The simplest form of postcorrelation analysis is called 'the method of cumulants' and provides for a mean particle size together with an index of polydispersity. If a defined *a priori* form of a distribution (as recommended in ISO 13321) is now assumed, the cumulants' result can now be expressed as a mean size  $x_{\text{pcs}}$  and standard deviation of a size distribution.

At this point it is necessary to point out that for particles substantially smaller than the wavelength of the illumination, the quantity of light scattered reduces as radius to the sixth power.

For a distribution of particles in this size region, any autocorrelation function is biased due to the higher photon contribution from the large particle fraction compared with that of the small sizes. This bias can be unweighted within the *a priori* distribution to provide a revised estimate of particle size  $x_{\text{vol}}$ .

For very small particles  $< \lambda/10$ , light scattering becomes proportional to  $x^6$ , and thus distributions having a range of sizes beyond 10:1 are problematic.

In order to obtain further information about the nature of the distribution, without an *a priori* assumption of its shape, more sophisticated data analysis schemes are implemented. The most popular method is called CONTIN. This is a freely available program.

Further routines follow a route of nonlinear least squares, whilst an exponential sampling method and singular value analysis routine have also been tried.

### Operational Limitations of PCS

The smallest particle size that can be measured is determined by the cleanliness of the sample preparation, the input laser power, and/or detector

quantum efficiency (scattering  $\sim x^6$ ). The cholesterol molecule, with a diameter of approximately 0.6 nm with a molecular weight of 387 Da, has been measured.

The largest particle that can be measured depends upon its density. The technique observes Brownian motion, and is perturbed by the influence of sedimentation.

The resolution of the technique should be considered as low to medium. A bi-modal mixture whose sizes are different by a factor of 2 can be resolved under favorable conditions.

An important assumption for fundamental particle sizing by PCS is that the particles be noninteracting. It has been previously stated that particles are assumed to be in a dilute suspension. In order to ensure that this condition applies, a series of measurements is recommended at increasing dilutions to demonstrate that particle interaction be absent.

To be able to conduct particle size determinations at high concentration is very advantageous. Measurements are now conducted at high concentration using a variation of the PCS technique and others. These can be conducted with particle systems having concentrations of up to 40% by weight.

It is important to realize that such particle size determinations at high concentration may or may not be influenced by particle–particle interactions and the influence of multiple scattering. It is also possible that the dynamic viscosity of the suspending medium is also hindering the particle motion leading to an oversize estimation.

The value of viscosity used to make the particle size calculation may not be the true viscosity. Used in this way the value entered for viscosity should be considered a calibration factor used to report the particle size that has been previously determined by a fully dilute experiment.

### Applications

These have thus far included studies of the following systems: proteins, microemulsions, colloids, copolymers, micelles, liposomes, fibrinogen, internal molecular motions, liquid interfaces, fatty acids, viruses, bacteria, vesicles, viscosity, lipids, motile cells, enzymes, lipoprotein, polyelectrolytes, spores, liquid crystals, glass transmissions, sols, microgels, soot, blood plasma, nanoparticles, swelling latex, gene delivery, and intravenous fat emulsions.

### Sedimentation

This method of measuring particle size distributions exploits the way that objects settle very slowly in a fluid under gravity or centrifugal force.

The International Standard ISO 13317, parts 1–3, inclusive cover this method.

Particles of sand or mud are transported in flowing water and settle in strata by much the same method. The sedimentation method, although not as quick or convenient as other techniques, finds favor with geologists and other mineral processors.

Sedimentation assumes a spherical particle assumption to relate settling speed with particle size that does result in a bias of the size reported for nonspherical particles.

Natural sediments consist of many differing minerals having differing shapes and densities. Despite this, considerable experience of natural sediments has been gained using sedimentation size distributions to create empirical predictive models of the movement and deposition of silts and mud.

### Theory

The illustration in Figure 4 is of a spherical particle settling very slowly in a fluid.

A particle having a higher density to that of the suspending fluid accelerates under the influence of gravity. It reaches a terminal velocity as a result of the drag force exerted by the liquid's viscosity operating upon the total wetted surface of the particle. The resulting terminal velocity is described by the Stokes equation provided the limits of creep flow ( $Re < 0.25$ ) are obeyed:

$$u_{st} = \frac{(\rho_s - \rho_l)gD^2}{18\eta}$$

where  $U_{st}$  is the Stokes settling velocity,  $\rho_s$  the particle density,  $\rho_l$  the liquid density,  $D$  the particle diameter,  $\eta$  the liquid viscosity, and  $Re$  the Reynolds number.

During the derivation of the Stokes equation the simple relationship between the mass of a

homogeneous sphere being proportional to  $D^3$ , whilst the drag due to the surface area is proportional to  $D^2$ , results in this simple equation. For irregular particles the solution is more complex and thus a spherical equivalent particle diameter is reported.

With a thin disk-shaped particle, the surface area will have a much greater influence than that of its mass. A disk-like particle will settle very much more slowly due to it experiencing a higher drag relative to its mass and thus may be undersized.

### Instrumental Implementations

A patent was granted in 1969 for a gravity, X-ray, sedimentation design. A predispersed sample is introduced into a temperature controlled measurement cell. Observations are taken of the incremental change in concentration or density, with respect to time, of the sample at a specific point within the cell. These observations are made by either X-ray or light scattering extinction techniques (Figure 5).

There are two main modes of operation.

**Line start** Here the sample is introduced as a thin layer onto the surface of the liquid suspending medium. The line start method is more often

**Figure 4** Forces acting upon a settling spherical particle.

**Figure 5** Block diagram of a typical sedimentation unit.

applicable to centrifugal sedimentation. For some materials, where the line start can be applied, higher-resolution results may be possible.

This is due to the particles being segregated by size making the quantity determination more precise.

As the largest size particles experience the gravitational or centrifugal force the greatest they not only settle in the fluid but also are separated from their neighbors.

**Homogeneous start** Here the sample is added to the suspending medium and made homogeneous by stirring prior to the commencement of the measurement. The sample preparation may be carried out in a beaker, the suspension then being pumped into the measurement cell and the pump stopped prior to the measurement sequence.

### Practical Considerations

Natural sediments and minerals often contain heterogeneous populations of sizes, shapes, and densities. The average value of density to be employed for particle size calculations should be the specific gravity and not the absolute density. The use of specific gravity for the value of density avoids additional and unnecessary errors in the reporting of size due to the presence of surface and internal unwetted porosity.

Any gas trapped within the pores of a particle will contribute to additional buoyancy. If the creep flow requirements are to be met in the presence of samples having a distribution of sizes, then care must be taken to ensure that the largest particles settle sufficiently slowly. This is often achieved by increasing the viscosity of the suspending fluid. More viscous suspensions may well hinder the creation of reliable dispersions.

The temperature of the dispersed sample needs to be controlled to within 1°C and known in order that an appropriate value of viscosity is employed.

The duration of the measurement depends upon the width of the size distribution being evaluated. In general, the measurement time is proportional to  $1/D^2$ . In some implementations the cell is moved slowly during the data collection phase. This can reduce the overall measurement time but at some risk to the final resolution.

### Electrical Sensing Zone Method

In this method the change in conductivity of a liquid by the presence of a particle is exploited. The origins of the technique lie in a method of counting fish passing through a salmon ladder.

Particles are homogeneously suspended in an electrically conducting fluid and caused to flow through a

**Figure 6** Principal components of an electrical sensing zone unit.

small aperture in an insulating wall. The small current passing through this aperture changes when a particle is present within the aperture.

The International Standard ISO 13319:2000, Determination of particle size distributions – Electrical sensing zone method, covers this method.

The experimental setup is shown in Figure 6.

As the particle passes through the aperture, it displaces an equivalent volume of electrolyte, so the change in current or a voltage pulse derivative responds directly to the volume of the particle. The electrical response of the aperture is calibrated, either by passing a range of certified particles of known size through the instrument, or by a mass integration technique.

The use of certified reference particles provides a means of validation.

As particles are examined one by one a highly resolved distribution by number can be established. The number of particles recorded in each size class can be readily totaled to form a distribution by volume. If the total volume of suspension fluid passing through the aperture is also recorded then the number of particles per unit volume of suspension can also be obtained. This feature has provided an important tool in medicine in being able to count red, white, and platelet cells from blood samples.

Apertures having different diameters may be fitted into the instrument to accommodate samples of different size ranges. The dynamic range of particle size that can be handled by a single aperture is ~40:1.

The concentration of particles within the suspending fluid must be restricted to very dilute levels in order that coincidence of particles appearing in the aperture is kept to a very low level such that a distorted result is avoided.

If a distribution by volume is desired then further care must be exercised to ensure that an adequate number of particles are counted. This requires sufficient experiment time whilst a substantial quantity of suspension flows through the aperture.

The lower size limit is stated to be just less than  $1\text{ }\mu\text{m}$ . This restriction is imposed by the noise limit of pulse detection.

Care must be exercised when dealing with a particle that is either conducting, or that has continuous pore structures, if additional errors are to be avoided.

A substantial bibliography exists on suitable electrolyte mixtures, many of which are cited in the ISO standard.

### Image Analysis

The rapid technological advance in small computer systems, imaging cameras, and light sources is driving a major advance in this technique for particles of a few micrometers and above. Dynamic image collection and rapid data storage for immediate or subsequent analysis is rapidly replacing fixed image analysis from particles deposited upon a substrate.

Both static and dynamic image analyses are supported by ISO 13322 parts 1 and 2 currently in preparation.

For submicrometer particles, where electron microscopy is employed, advances will be more modest. Here fixed image analysis remains the norm.

Image analysis provides a method where size distribution is obtained together with valuable shape data from essentially two-dimensional objects. Dynamic image analysis from randomly orientating particles of large numbers of two-dimensional objects offsets the influence of having only a two-dimensional observation, to some degree.

By far the majority of industrial particle size distributions are required to be presented as distributions by volume. It should be remembered that a single  $100\text{ }\mu\text{m}$  particle has the equivalent volume of 1 million,  $1\text{ }\mu\text{m}$  particles.

In the past, the image analysis technique has been found tedious and expensive on preparation time to provide a sufficiently high count of particles. This is necessary to support statistically justified distributions by volume for polydisperse samples.

The contrast of the particle image depends upon its optical properties with respect to the suspending medium and the method of illumination.

**Figure 7** Image of a particle and pixel representation.

Software mechanisms have been developed in order that a representation of the true boundaries of the particle is established. Images of touching particles are either software segregated or rejected from the analysis. Out-of-focus objects are also rejected by software techniques. A binary array, where the shadowed pixels are 1 in a background of 0, is often employed to permit rapid data storage and image analysis (Figure 7).

The image of a two-dimensional irregular shaped object can be reduced to a dimension of size by an array of methods. The choice of method will influence the final reported size distribution and varies from unit to unit. It is therefore necessary to report the method chosen if confusion of results from different machines is to be avoided.

Calibration is achieved by the use of a reference reticle.

The size range covered is set by the imaging optics together with the resolution and pixel area of the camera employed. As the particle image approaches the size of a single pixel the resolution of size degrades rapidly. This, coupled with the optical arrangement, defines a lower limit.

The upper size is determined as to whether the image of such a large particle is wholly captured within the frame.

Some implementations employ a line-scan camera observing a stream of dispersed particles falling at a constant velocity. The above size range restrictions continue to apply.

Particle size results are sometimes portrayed in three-dimensional form where a sphericity or shape-determining factor is displayed as the third axis. An example is shown in Figure 8. Images of the particles are often made available for visual examination.

### Sieves and Sieving

The segregation of various sizes of particles using woven cloth screens can be traced back as far as the ancient Egyptians where the method was used to separate seeds from other detritus.

**Figure 8** Three-dimensional graph of sphericity versus particle size.

Many materials such as sands, gravels, road stone are sold in specified size fractions, prepared by screening.

ISO 2591-1:1998 (Test sieving – Part 1: Methods using test sieves of woven wire cloth and perforated metal plate) covers the sieving method.

Sieves are either made from woven wire, punched plate, or are electroetched, as illustrated in Figure 9.

A substantial range of apertures is available, classified as coarse (4–100 mm), medium (0.2–4 mm), and fine (less than 0.2 mm). The sieve sizes often follow a size progression based upon the fourth root of 2. Other progressions such as a 10th root of 10 have also been employed. The lower size of woven wire sieves is  $\sim 37 \mu\text{m}$ . A specialized range of micromesh sieves is produced with sizes down to 1–2  $\mu\text{m}$ .

Aperture shapes approximate to squares for woven sieves. Punched or etched sieves can be of any shape in principle but are either square or round in practice.

The sieving process may be carried out on either dry or wet samples, shaking by hand or by machine. Sieving is either carried out for a fixed time or until the sample passes through the sieve at a low but constant rate. This latter approach is not usually adopted for stacked sieves.

The weight of sample retained upon the sieve is required. This is sometimes achieved by the following method.

Accurate weights of the clean sieves prior to a measurement are made. A second weighing of the sieve and the retained sample fraction remaining on the sieve at the conclusion of the sieving process is also made.

The results from a sieving operation are influenced by the following factors:

- the shape of the sieve aperture;
- the load of powder to be sieved;

**Figure 9** Illustration of woven wire and punched plate sieves.

- the duration of sieving;
- the cohesiveness of the powder sample;
- the presence of fine particles;
- the particle shape;
- the friability of the sample;
- the agitation method.

The time of sieving is closely related to the sieve loading that in turn is influenced by the precision required for the retained weight of sample on each sieve. Some trial runs will be necessary before an optimum strategy for the material in question is achieved.

### Dry Sieving

The size distribution, particularly the presence of fines, and the cohesive properties of the powder are key elements to consider if sieving is to be adopted. Aggregates may be reduced by drying or by the addition of a small quantity of flow enhancing agents such as silica or stearic acid.

Air-jet sieving apparatus enhances the process of sieving by fluidizing the powder in order that it may more readily pass through a bank of sieves. Sonic sifting is also applied in some implementations.

**Wet Sieving**

This method is applied to particle systems that are already in suspension or that are prone to aggregate. The sample is washed or rinsed through a nest of sieves whilst agitation is being applied. Additionally, sonication and vibration may also be employed.

One method of analysis requires that on completion of the sieving process the retained sample on each sieve be rinsed off into a collecting dish of known tare weight and dried in an oven. The final retained weight of sample is then deduced.

**Sieve Calibration**

Spherical particles such as glass beads are often to be found retained in the mesh of woven sieves at the conclusion of a sieving process. If the size distribution of these retained particles is carefully measured using a calibrated microscope then an estimate of the range of mesh sizes for a particular sieve can be obtained.

**Sieve Cleaning**

It is during the process of cleaning that sieves often become damaged. Loose dry powder may be gently removed with a very soft camel haired brush. In order to ensure a reasonable open area, fine mesh sieves are made with finer gauges of wire and are thus more vulnerable to damage. Cleaning by gentle rinsing may be sufficient. Cleaning by immersion in an ultrasonic bath may be used; again the finer mesh sieves are vulnerable to ultrasound damage. Particles trapped within the mesh may be dissolved with some materials. The temptation with trapped particles is to poke them out with a sharp point. This practice is to be avoided at all costs as it invariably widens one or more mesh holes.

### Introduction

A peptide is a molecule formed by the condensation of a small number of amino acids, of general formula

They are often obtained from the breakdown of proteins.

The analysis of peptide structure is central to the enormous advances made in the last 20 years in all aspects of biomedical sciences. The advances in peptide and protein chemistry have been accompanied by the development of a range of analytical procedures that in turn have accelerated the progress made in the understanding of, for example, hormone–receptor interactions and antigen–antibody interactions.

The vast majority of peptides currently produced are generated by solid-phase peptide synthesis (synthetic peptides) or from the enzymatic or chemical digestion of proteins. The procedures that are commonly used in the analysis of peptides can be divided into four stages: (1) purification, (2) composition and sequence analysis, (3) conformational analysis, and (4) biological analysis. For synthetic peptides, purification procedures are generally of routine nature and amino acid composition and sequence analysis are used to confirm the identity of the synthetic product. The purified peptide samples are then subjected to conformational analysis and biological evaluation to establish the structure–function relationships in the particular biological system. Peptides derived from the enzymatic or chemical digestion of protein (i.e., peptide mapping) are generally prepared in order to derive partial sequence information of a newly isolated protein or, in the case of a recombinant protein, the combined sequence analysis of all peptide fragments can be used to verify the structure of that protein. A wide variety of experimental techniques are now routinely used in the determination of peptide structure. This article deals only with the first three stages of peptide analysis, as a detailed overview of the range of biological assays commonly used to determine the activity of a peptide is outside its scope.

## Purification

### Liquid Chromatography

The most commonly used method for the analysis and purification of peptides mixtures is reversed-phase liquid chromatography (RPLC). The experimental system usually comprises an *n*-alkylsilica-based stationary phase material from which peptides are eluted with gradients of increasing concentration of acetonitrile in the presence of ionic modifier, e.g., trifluoroacetic acid (TFA). With modern instrumentation and columns, complex mixtures of peptides can be separated and low picomole amounts of resolved components can be collected. Separations can be easily manipulated by changing the gradient slope

**Figure 1** Reversed-phase liquid chromatographic profile of a tryptic digest of bovine growth hormone on a C18 silica column, particle diameter 5  $\mu$ m, average pore size 30 nm packed into 25 cm  $\times$  4.6 mm ID columns. Gradient elution was carried out from 0% to 50% acetonitrile in 0.1% TFA over 60 min at a flow rate of 1 ml min<sup>-1</sup>. Detection was by absorbance at 215 nm.

or organic solvent composition. The technique is equally applicable to the analysis of enzymatically derived mixtures of peptides and also for the analysis of synthetically derived peptides. An example of the analysis of a tryptic digest of bovine growth hormone is shown in **Figure 1**. This figure demonstrates the rapid and highly selective separation of tryptic peptides of proteins that can be carried out by RPLC. The chromatographic separation shown in **Figure 1** was obtained with an octadecylsilica (C18) stationary phase. Separations can also be carried out with other reversed-phased sorbents, e.g., octylsilica (C8) or butylsilica (C4). Fractions collected during the separation can be subjected to further analysis as described below. For the purification of synthetically derived peptides, the crude synthetic product is separated initially on an analytical scale to assess the complexity of the mixture. This is usually followed by large-scale purification and collection of the product, and an aliquot of the purified sample is then subjected to further chromatography or mass spectrometry to check for homogeneity. An example of this procedure is illustrated in **Figure 2** for the purification of a synthetic analog of a human growth hormone-related peptide.

A major requirement in the purification of peptides generated from previously uncharacterized proteins is to maximize the detection sensitivity due to limited supplies of the proteins. Separations by RPLC are now carried out with narrow-bore columns of 1–2 mm internal diameter which increases the solute concentration thereby increasing the sensitivity. Further miniaturization of RPLC systems has also been achieved with the use of capillary columns of internal diameters of 0.32–0.075 mm.

**Figure 2** Reversed-phase elution profiles illustrating the purification of a synthetic peptide. (A) Analytical profile (100 µg) of a crude peptide mixture from solid-phase peptide synthesis. Chromatographic conditions as in (A).

## Capillary Electrophoresis and Electrochromatography

Capillary electrophoresis (CE) is a technique that is particularly suitable for the analysis of peptides that differ in net charge. As such CE is therefore a technique that is complementary to RPLC. It involves the separation of peptides by application to a fused silica capillary (typically 100 cm × 100 µm). Electrophoretic mobility is controlled by an external electric field and selectivity can be manipulated by a number of factors including solvent pH, ionic strength, and other additives. CE eliminates the need for organic solvents and extends the experimental working pH range above that of most silica-bonded stationary phases used in RPLC. Before the development of CE, very high sensitivity electrophoresis of peptides in the nanogram range was not generally performed. However, CE can be used to rapidly assess (typically in less than 15 min) the purity of synthetic peptides. CE also provides alternate selectivity to RPLC for the separation of peptides. For example, **Figure 3** shows a typical CE analysis of tryptic digest fragments of salmon calcitonin. The use of various ionic additives, e.g., hexylcetyldimethylammonium salts, provides a useful extension of CE procedures with polar peptides.

High-performance capillary electrochromatography (HP-CEC) is a tool that is complementary to capillary LC and CE and has been recently

**Figure 3** Analysis by CE of the tryptic fragments of salmon calcitonin. (Reprinted with permission from Camillieri P, Okafo GN, Southan C, and Brown R (1991) Analytical and micropreparative capillary electrophoresis of the peptides from calcitonin. *Analytical Biochemistry* 198: 36–42; © Elsevier.)

applied to the analytical separation and analysis of peptides. The technique involves the electrokinetic separation of components through a capillary packed with microparticulate stationary phase.

## Composition, Sequence, and Molecular Weight

### Amino Acid Analysis

Amino acid analysis has played a crucial role in the elucidation of peptide and protein structure. However, with the advent of mass spectrometric sequencing, it is now used less frequently. Following purification, peptide samples are hydrolyzed to the constituent amino acids in the presence of strong acid and heat. After hydrolysis, the amino acids are separated by RPLC and detected by precolumn derivatization with a fluorogenic reagent or by postcolumn derivatization with ninhydrin. The composition of the resulting amino acids should agree with the predicted integer number for the constituent amino acid residues. **Table 1** lists the amino acid composition of two of the chromatographic peaks in **Figure 1** derived from the tryptic digestion of bovine growth hormone. The data presented in **Table 1** generally provide unambiguous identification and assignment of tryptic fragments. However, deviations from the true integer value can be observed for some amino acids such as threonine, serine, tryptophan, and methionine.

**Table 1** Amino acid composition data for two tryptic peptides derived from bovine growth hormone

### N-Terminal Sequencing

Peptide sequence information is crucial for a number of applications including (1) fingerprinting recombinantly derived proteins, (2) complete protein structure determinations, (3) disulfide bond assignment, (4) identification of post-translational modification sites, (5) epitope mapping, and (6) construction of oligonucleotide probes for molecular cloning. The N-terminal sequencing procedure developed by Edman and Begg has been routinely used to determine the sequence of a peptide. While mass spectrometry (MS) has also significantly impacted on the use of Edman degradation for peptide sequencing, it is often used to sequence peptides that cannot be sequenced by MS, including hydrophobic peptides and samples containing high levels of detergent. Briefly, the procedure entails coupling of the Edman reagent phenylisothiocyanate (PITC) with the amino group of the terminal amino acid residue. The PITC-derivatized amino acids are then cleaved from the protein (exposing the next amino acid derivative and converted to the more stable phenylthiohydantoin amino acid derivative). The identity of the amino acid derivative is then determined by RPLC. The sequencing cycle is then continued with the PITC coupling step with the second amino acid, and so on. The major constraint in determining the amino acid sequence of subfemtomole quantities of a peptide is the ability to purify and manipulate the samples at these very low levels. The generation and subsequent purification of peptides following protein fragmentation often requires

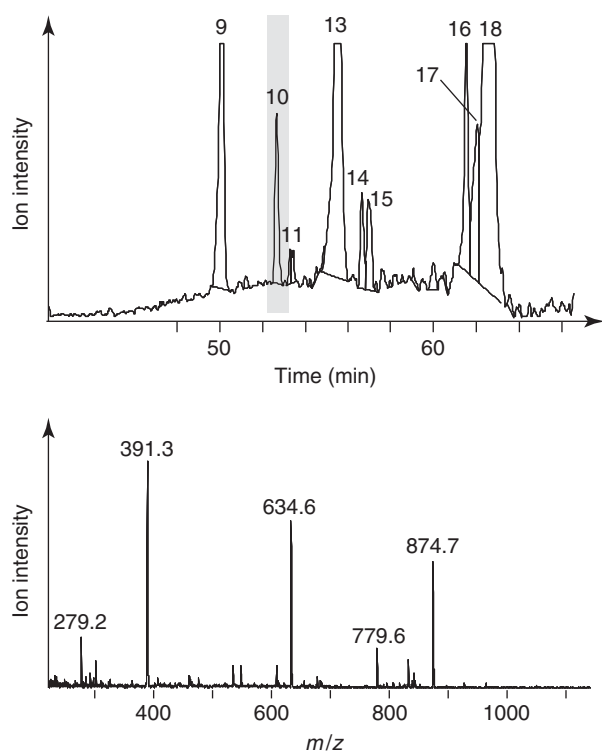

a number of micromanipulation steps such as desalting after reduction and alkylation, concentration, and buffer exchange into solvents used for further protein fragmentation. Narrow-bore or capillary chromatography is therefore now routinely used for the isolation of peptide fragments for sequence analysis.

### Mass Spectrometry

MS has emerged as a central tool for peptide structure analysis because of a number of important features. Identification in MS is based on the precise measurement of the mass-to-charge ratio from which the molecular mass of the peptide can be derived. The application of MS to the determination of large biomolecules is possible due to the development of new techniques for the ionization and detection of large polar nonvolatile molecules. The two ionization methods typically used for peptide analysis include electrospray ionization (ESI) and matrix-assisted laser desorption ionization (MALDI). Accurate molecular weight information can now routinely be determined on femtomolar and in some cases attomolar amounts of peptide. MS has largely superseded Edman sequencing procedures for the determination of amino acid sequence. In addition, the mass resolution and fragmentation allow post-translational modifications and other chemical modifications to be detected such as phosphorylation, sulfation, deamidation, and aspartic acid isomerization.

### Liquid Chromatography–Mass Spectrometry

With the widespread availability of sensitive mass spectrometric detectors suitable for online analysis of liquid chromatographic separations, LC–MS-based approaches are now the preferred option for chromatographic detection. The informational content of the ion chromatogram (ion intensity versus retention time) far supersedes the content of spectrophotometric detection. Moreover, the ability to resolve the peaks of the ion chromatogram into individual mass components gives instant compositional analysis and with instruments capable of performing MS/MS analysis sequence information of peptides during the separation can provide absolute identification. LC–MS is also used to quantitate species from relatively complex mixtures following appropriate standardization. An example of LC–MS analysis of a tryptic digest of cytochrome *c* is shown in **Figure 4**. Separation of tryptic fragments is easily achieved and individual species identified based on their characteristic masses, which can be predicted from the primary sequence of the protein. In addition to

**Figure 4** LC-MS of a cytochrome *c* tryptic digest. About 400 fmol of cytochrome *c* was digested with trypsin and the resulting peptides separated on a LC Packings PepMap C18 column (300 ×  $\mu$ m ID × 5 mm length). The upper panel shows the total ion chromatogram recorded on an Agilent 1100 MSD ion trap fitted with a nanospray source. The ion chromatogram approximates the UV chromatogram, but is significantly more sensitive, no signal was observed in this instance by absorbance at 214 nm. The highlighted region of the chromatogram was displayed as a mass spectrum (lower panel), revealing the presence of three major tryptic fragments in the single peak and revealing the enhanced informational content of this form of analysis.

quantitation and identification, such mass spectral detection can be used in split flow systems to switch from fraction collection to automate peptide purification postsynthesis or from natural sources.

### Peptide Sequence Determination Using Mass Spectrometry

Modulating the conditions of ion formation and subsequent manipulation of these ions can induce fragmentation during both MALDI and ESI. In the case of peptides, nested sets of ion fragments are formed from which amino acid sequence information can be derived (see **Figure 5**). For ESI-based techniques, tandem mass spectrometry or MS/MS instrumentation can be used to generate and analyze fragments. These instruments consist of two mass analyzers arranged in tandem and separated by a collision cell. Thus, in an MS/MS instrument the

**Figure 5** Fragmentation of peptides during postsource decay and collision induced dissociation. The peptide bond is sensitive to cleavage producing N-terminal a-, b-, and c-series ion fragments and C-terminal z-, y-, and x-series ion fragments. These cleavage patterns provide sequence information for oligopeptides, which yield a nested set of N- and C-terminal fragments from which sequence information can be readily derived. PSD fragments observed for a HLA B27-bound peptide isolated by immunoaffinity chromatography and RP-LC (5), highlight sequence information gleaned by fragmentation in MS. (Reprinted with permission from Purcell AW and Gorman JJ (2001) The use of post-source decay in matrix-assisted laser desorption/ionisation mass spectrometry to delineate T cell determinants. *Journal of Immunological Methods* 249(1): 17–31; © Elsevier.)

first mass analyzer can be used to select a particular ionic species of defined mass. The selected ion is subsequently channeled into the collision cell that usually contains an inert gas. Collision with the gas molecules induces fragmentation and ion fragments are analyzed in the second mass analyzer. The most common instruments of this type of collision-induced dissociation (CID) MS/MS experiment are the triple quadrupole instruments. Other types of mass analyzers may be used in tandem

such as those used in hybrid instruments such as electrospray ionization–quadrupole–quadrupole–time-of-flight MS and four-sector MS/MS instruments. Another type of mass analyzer that is useful for MS/MS experiments using ESI sources are the ion-trap instruments.

Fragmentation of ions in MALDI need not involve CID, since the conditions of MALDI and ion acceleration may be changed to induce fragmentation in the ion source (in-source decay or ISD) or after leaving the ion source (postsources decay, PSD). Laser intensity is varied to induce both ISD and PSD, which are both mediated by collisions with the matrix cloud formed by MALDI. An inert gas may also be used in the source to induce CID fragmentation during MALDI. ISD of peptides and proteins is induced by performing MALDI at very high laser irradiance and retaining the ion in the source to decay by using a longer than usual period of delayed extraction, it is therefore essential to have pure samples for such analysis. In contrast, short delay times are used to be able to observe PSD ions. Both CID and PSD fragment ions form after leaving the ion source and can be only analyzed in a TOF instrument fitted with a reflectron. The reflectron potential is changed systematically to disperse the PSD fragment and parent ions. Spectra are collected at different reflector potentials if the instrument is fitted with a multistage or linear reflector and the spectra stitched onto a single continuous mass range, or as a single spectrum using a curved field reflectron.

## Conformational Analysis

Central to the understanding of peptide structure–function relationships is the characterization of peptide conformation. The amino acid sequence predisposes the peptide chain to adopt several conformations in aqueous and lipid environments. The ultimate goal of the investigator is therefore to determine the relationship of these solution structures to the biologically active conformation. This knowledge provides information on the molecular factors involved in the action of the peptide. Ultimately, conformational analysis is an integral part of the rational design and synthesis of peptide analogs and has led to the development of improved therapeutic substances.

### Circular Dichroism Spectroscopy

Circular dichroism (CD) spectroscopy is the most extensively used technique for the rapid evaluation of peptide secondary structure. The far-UV region

of the CD spectrum, which corresponds to the amide bond region, is used to interpret peptide secondary structure. Deconvolution of the CD spectra between 190 and 240 nm provides an indication of the relative contributions of  $\alpha$ -helix,  $\beta$ -sheet,  $\beta$ -turn and random coil structures to the overall spectrum. The diagnostic signal of an  $\alpha$ -helix is a strong negative ellipticity (Cotton effect) at 208 and 222 nm. The CD spectrum for the antimicrobial peptide magainin II and a potent analog is shown in **Figure 6**; a negative ellipticity between 208 and 222 nm, which is characteristic for an  $\alpha$ -helix, is clearly evident. The interpretation of these spectra depends on the presence of a significant population of helical conformations. For short peptides with less stabilized structure and with highly flexible N- and C-termini, the presence of  $\alpha$ -helix may be difficult to detect. The presence of significant populations of  $\beta$ -sheet structure is indicated by a negative ellipticity at 215 nm. The presence of  $\beta$ -turns in a peptide can be determined by the positive ellipticity at 200–210 nm for type II turns while type I turns exhibit similar spectra to  $\alpha$ -helices.  $\beta$ -Turns are most easily detected in the CD spectra of small peptides as the measured  $\beta$ -turn ellipticity in larger peptides is masked by the signals from the rest of the peptide. The recent development of synchrotron radiation CD has resulted in significant enhancement of spectral quality and will undoubtedly lead to improved structural information.

While CD provides a procedure for the rapid determination of secondary structure, it does not provide information in the precise location of the secondary structure within the peptide. This information is more readily obtained from nuclear magnetic resonance (NMR) spectroscopy.

**Figure 6** Circular dichroism spectra of magainin 2 and ala<sup>8,13,18</sup>-magainin analog measured in 0.02 mol l<sup>-1</sup> phosphate buffer (pH 7.4) containing dimyristylphosphatidylcholine/dimyristylphosphatidylglycerol/cholesterol (70:15:15) liposomes.

**Figure 7** Infrared spectra in the amide I and amide II regions of alamethicin (solid line) and an alamethicin analog (dotted line) in methanol. (From Haris PU, Molle G, and Duclohier H (2004) *Biophysical Journal* 86: 248–253; © Biophysical Society.)

### Fourier-Transform Infrared Spectroscopy

Fourier-transform infrared spectroscopy (FTIR) provides significant value in the analysis of peptide conformation. The most commonly used spectral band is the amide I stretching vibrations of the backbone carbonyl groups. The vibration frequency is related to the degree of hydrogen bonding that is determined by the local secondary structure. **Figure 7** shows the infrared spectra (in methanol) in the amide I region of the potent antimicrobial agent alamethicin and an analog in which all eight amino-isobutyric acids have been replaced. While the spectra in the amide I and amide II regions are similar for both peptides, the amide I bands at 1660 and 1663  $\text{cm}^{-1}$  indicate differences in peptide conformation. Spectra can also be obtained in a range of solvent conditions including the presence of phospholipids. Vibrational spectroscopy has the potential to provide information on the relative conformations of a particular peptide. These analytical techniques thus complement NMR spectroscopy which gives site-specific information.

### NMR Spectroscopy

NMR spectroscopy now represents the major tool for the precise determination of the conformation of peptides in different solution environments. Detailed information on the molecular geometry of peptides in terms of bond angles can be determined to a high degree of accuracy. However, owing to the long time-scale of the measurements, the

**Figure 8** Two-dimensional nuclear Overhauser enhancement spectroscopy  $^1\text{H}$  NMR spectrum of hGH[6–13] related peptide showing the nuclear Overhauser effect connectivities between a phenylalanine ring ( $\text{C}_6\text{H}_5$ ) and an alanine methyl ( $\text{CH}_3$ ) and methine (CH) protons).

structural information is a population-weighted average over all structures in the conformational repertoire of the peptide.

The most important structural probe is the nuclear Overhauser effect (NOE), which provides valuable information on the structure of linear peptides. Briefly, the observation of a direct NOE between a pair of protons indicates the presence of a significant population of conformers in which the distance between these two protons is relatively short. The overall pattern of connectivity therefore corresponds to a particular conformation. Constraints on both backbone and side chain dihedral angles are obtained from coupling contacts. An example of a two-dimensional NMR spectrum for a synthetic peptide related to residues 6–13 of human growth hormone is shown in **Figure 8**.

## Introduction

The use of perfumes goes back thousands of years. The Egyptians used plants, gums, and resins in religious rites. As the years went by, scented substances were used to enhance body attractiveness and to make homes and public places more pleasant.

Fragrances are considered normal components of our everyday lives. Many people feel the need to wear a fragrance in order to feel good: this is probably because there is a connection between scent and emotion as well as between scent and memory; moreover, studies have shown that some fragrances can alter moods and even alleviate anxiety and stress.

Perfumes can be defined as substances that emit and diffuse a pleasant and fragrant odor. They consist of manmade mixtures of aromatic chemicals and essential oils. Until the nineteenth century perfumes were usually composed of natural aromatic oils.

Nowadays, most perfumes are synthetic and may contain many components.

This article deals with the different types of products containing perfumes, raw materials, legislation and safety aspects, analytes of interest, and analytical techniques.

## Types of Products Containing Perfumes

Perfumes can be used in different types of products (Figure 1) such as cosmetics and toiletries (fine fragrances, shampoos, conditioners, hair sprays, shaving creams, makeup, baby care products, deodorants, soaps, feminine products, etc.) and household products (cleaners, air fresheners, bleaches, laundry detergents, fabric softeners, etc.).

### Cosmetics and Toiletries

Fragrance compositions used in cosmetics are complex mixtures of hundreds of ingredients, which together give a compound its unique scent.

Fine fragrances are hydroethanolic solutions prepared from aromatic chemicals and essential oils. They are named according to the fragrance

**Figure 1** Types of products usually containing perfumes.

Parfum	12–18%
Eau de Parfum	8–12%
Eau de Toilet	5–8%
Eau Fraiche	4–5%
Eau de Cologne	3–4%
Cologne	2–3%
Baby Cologne	1–2%

**Figure 2** Approximate concentration of perfumes in different types of fine fragrances.

content (Figure 2): Parfum, Eau de Parfum, Eau de Toilette, Eau Fraiche, Eau de Cologne, Cologne, Baby Cologne. The last has a special formulation, with a very low content of fragrance and some hydrating ingredients added to give softness to the baby skin.

Perfumes are used in practically all cosmetics and toiletries, sometimes with a function secondary to the main one of the product but often solely to provide fragrance. For example, aftershave lotions and splash colognes usually contain 0.5–2% perfume oil.

### Household Products

A wide range of perfumes, predominantly based on synthetic ingredients, are used in household products. They are used to make cleaners smell more pleasant than their chemical ingredients. Some of the cleaners that usually contain fragrances in their compositions are softeners and laundry detergents, dish-washing products, floor cleaning products, furniture polish, and bathroom cleaners. Air fresheners also contain perfumes in their formulations.

Special problems can occur in the formulation of cosmetics and toiletries or household products containing perfumes (odors may be changed or may become unstable in the new medium, the perfume may change the physical properties of the cosmetic, etc.). Therefore, the fragrance must be formulated individually for each product.

### Types of Raw Materials

Raw materials used as perfumes include natural products (of plant or animal origin) and synthetic materials.

#### Natural Ingredients: Methods of Obtaining

Natural ingredients originate from materials found in nature. These are obtained through physical processes.

Vegetable products are obtained from different parts of plants – flowers (jasmine, rose, gardenia),

fruits (lemon, orange), roots (vetiver, cistus), leaves (violela, patchouli), wood (vetiver, sandalwood, cedarwood), bark (cinnamon, nutmeg), resin (benjui, tolu, galbanum), seeds (angelica, apio) – and whole plants (lavender, geranio).

Some animal secretions contain odoriferous substances that increase the diffusion and qualities of perfumes. Some of them act as fixatives, preventing the rapid evaporation of the most volatile ingredients of the perfume.

The most widely used animal products are ambergris (from the sperm whale), castor or castoreo (from the beaver), civet (from the civet cat), and musk (from the musk deer).

Different procedures can be used to obtain raw materials for fragrances from plants and animals.

Hydrodistillation is used to obtain essential oils (lavender, rose) from plants. Plants are boiled in water, and the essential oils are evaporated and dragged by the water vapor.

Solvent extraction is used for delicate flowers (e.g. jasmine). Thus, the damage caused by the high temperatures needed to boil water when using the hydrodistillation method is avoided. The concentrated flower oil is called absolute.

Soxhlet extraction can facilitate the extraction of essential oils in some cases. Supercritical fluid extraction (SFE) allows faster extraction, and moreover, use of supercritical fluids as extraction solvents allows, in some cases, a green extraction procedure.

In the extraction method called enfleurage, petals are placed between layers of purified animal fat, which become saturated with flower oil; alcohol is then used to obtain the absolute. This technique is carried out at low temperature; it is very costly and is rarely used today.

Maceration is similar to enfleurage. The flowers are steeped in vats of oil until the scented parts dissolve. The oil may be heated to speed up the process. Maceration is, however, very time consuming.

The expression method is used to obtain essential oils from fresh fruit peels (lemon, orange), it can be done either by using the traditional procedure of pressing with sponges or by mechanical maceration: as there is no heat involved, the smell of the oil is very close to that of the original plant.

Apart from these techniques there are various other operations such as rectification, fractional distillation, terpene removal, decolorization, etc., that improve and refine the numerous raw materials used for the blending and making of perfumes.

Natural ingredients coming from animal products are usually extracted using the alcohol maceration procedure.

## Synthetic Ingredients

Synthetic ingredients are manufactured through chemical processes. Diverse types of synthetic products are used as perfumes. The components of a great number of natural fragrances have been determined and then chemically synthesized to imitate natural perfumes. Artificial fragrances that do not imitate nature have also been used to create new perfumes.

Different organic groups have been used in synthetic perfumes: hydrocarbons, terpenes, sesquiterpenes, alcohols (citronelol, geraniol, cinnamic alcohol), fenols (*p*-cresol, thymol), aldehydes (cuminaldehyde, vanillin), ketones (carvone, muscone, ionones, metilionones), lactones (nonalactone, undecalactone), esters (acetates, formates, butyrates), nitrogen compounds (indol, methyl anthranilate, musk xylol, quinolines).

The main advantage of using synthetic products is that their costs are lower than those of natural products and they can always be obtained consistently without any problems related to poor crop quality or lack of supply or to difficulties using animal extracts, etc. In other words, artificial products cost less and represent fewer market variations.

The selection of raw materials depends on different questions such as the type of the desired odor, the users focused on, the particular application, the stability of the finished product, the approximate price desired for the final product, etc.

## Legislation and Safety

Both EU and US legislations stipulate that the ingredients of a cosmetic product must be listed on the label in order of predominance. There are a few exceptions to the labeling requirements, such as fragrance formulas, which are considered trade secrets: therefore the ingredients in fragrances are not required to be revealed. The word 'fragrance' must be included on any label of products in which ingredients have been added to give off an odor. This word on the label may represent many ingredients.

Many of the ingredients used in fragrances have had little or no safety testing done on them. Most of the safety testing that has been done revolved around the dermatological effects of fragrance chemicals. The effects on the respiratory system, the brain, and other organs of the body have not been determined for individual chemicals, much less in the combinations in which they are used.

Fragrance chemicals can be inhaled through the nose, ingested through the mouth, and absorbed through the skin. Once in the body they are absorbed into the bloodstream and transported throughout the body. Individual sensitivities to the effects of

fragrance chemicals vary widely from no effect at all to severe reactions. Different symptoms have been found in different people: skin sensitivity, rashes, dermatitis, coughing, asthma attacks, migraine, etc. The incidence of these effects can be studied in relation to the method of application: leave on skin, rinse off skin, non-skin contact, handling household products.

Different organizations such as the Research Institute for Fragrance Materials and the International Fragrance Association (IFRA) have been formed by the industry and have an important role in consumer protection. They carry out research on ingredients used in fragrances in order to ensure the safety of perfumery materials. Recent studies on criteria for safety evaluation are particularly interesting.

At the moment, EU legislation forbids the use of 36 fragrances as cosmetic ingredients; therefore, any other fragrance could be used. Since fragrance materials do not have to be declared on the label, it is impossible to know exactly which materials are in the product. This makes it difficult to ascertain which potentially problematic material is in any given product. Fortunately, a recent EU normative obliges manufacturers to declare on the labels the name of 26 ingredients that have been proven to be allergenic. This and similar initiatives in other countries should contribute to the consumer being better informed.

On the other hand, terms such as 'unscented' or 'fragrance free' have no legal definitions. A product labeled with these terms still contains fragrance chemicals, even if the scent cannot be easily detected, because if a fragrance is added to a product to mask or cover up the unpleasant odor of some ingredients, it need not be mentioned on the label.

In the same way, the term 'hypoallergenic' is sometimes used for some cosmetics. Perfumes are the substances mainly responsible for producing allergies, although some preservatives, dyes, ultraviolet filters, detergents, solvents, etc. can also be allergenic. Hypoallergenic cosmetics are products that manufacturers claim produce fewer allergic reactions than other cosmetic products. However the term has no legal definition, and consequently the use of a hypoallergenic product does not guarantee immunity to any allergic reaction.

## Analytes of Interest

As mentioned before, a perfume is a mixture of a lot of compounds that are responsible for an aroma; perfume manufacturers use ~1500 compounds. These compounds are chemically very different and can be grouped into different families according their chemical structure. **Table 1** shows some examples of these compounds.

**Table 1** Examples of compounds that could be present in a perfume composition, ordered according to chemical structure

Group	Compound
Alcohol	$\beta$ -Citronellal, eugenol, geraniol, linalool, menthol
Aldehyde	Benzaldehyde, citral, hexyl cinnamal, anisaldehyde, vanillin
Hydrocarbon	Nonane, tetradecane, camphene
Terpene	Limonene, myrcene, $\alpha$ -pinene
Sesquiterpene	Caryophyllene
Ester	Methyl salicylate, menthyl lactate, terpineol acetate
Ether	Anethole, eucalyptol
Ketone	Cyclohexanone, camphor
Lactone	Coumarin, 6-methyl-coumarin, $\gamma$ -undecalactone

Analytical control of the components in perfume formulations ensures that the final product has the desired fragrance.

Other compounds that are permitted but can still cause health problems and must be declared on the label have a special analytical interest. For instance, **Table 2** shows 26 potentially allergenic substances whose presence in the formulation has to be advertised according to legislation. Of these 26 substances, two are natural extracts (oak moss and tree moss), and the rest are volatile chemicals. Recently, the IFRA has developed an analytical procedure that allows the determination of these 24 volatile chemicals using gas chromatography (GC) coupled with mass spectrometry (MS).

## Preparation of Samples for Analysis

Sample preparation depends not only on the type of sample but also on the analytical technique used for analysis.

Sometimes sample pretreatment is not necessary due to the simplicity of some of these samples, and they can be injected directly in a GC system. Due to the volatile nature of the compounds present in a perfume, the headspace (HS) sampling mode is also often employed to introduce the compounds to be determined in the GC system.

However, a previous distillation is sometimes needed to separate the target compounds from a complex matrix sample. After they are condensed, they can then be either injected directly or through the HS mode. In other cases, the use of extraction techniques like solvent-solvent extraction, solid-phase extraction, and solid-phase microextraction not only achieves the isolation of the target compounds from the matrix but also produces a preconcentration of

**Table 2** Potentially allergenic fragrances that have to be declared on the labels of cosmetic formulations according to EU legislation*Compound (Chemical Abstracts Service Registry Number)*

Amyl cinnamal (122–40–7)	Anisyl alcohol (105–13–5)
Benzyl alcohol (100–51–6)	Benzyl cinnamate (103–41–3)
Cinnamyl alcohol (104–54–1)	Farnesol (4602–84–0)
Citral (5392–40–5)	2-(4- <i>t</i> -Butylbenzyl) propionaldehyde (80–54–6)
Eugenol (97–53–0)	Linalool (78–70–6)
Hydroxycitronellal (107–75–5)	Benzyl benzoate (120–51–4)
Isoeugenol (97–54–1)	Citronellal (106–22–9)
Amyl cinnamyl alcohol (101–85–9)	Hexyl cinnamaldehyde (101–86–0)
Benzyl salicylate (118–58–1)	Limonene (5989–27–5)
Cinnamal (104–55–2)	Methyl heptin carbonate (111–12–6)
Coumarin (91–64–5)	3-Methyl-4-(2,6,6-trimethyl-2-cyclohexen-1-yl)-3-buten-2-one (127–51–5)
Geraniol (106–24–1)	Oak moss extract (90028–68–5)
Hydroxymethylpentyl- cyclohexenecarboxaldehyde (31906–04–4)	Tree moss extract (90028–67–4)

the analytes. (HS-solid-phase microextraction–GC has been applied successfully to the determination of perfume components in different household products such as scented candle wax, liquid detergents, and fabric softeners.)

## Analytical Techniques

In the past, quality control of perfumes was done by measuring physical properties like the refractive index, density, and optical rotation, in addition to very simple chemical tests like acidimetry and measurement of the saponification and carbonyl indexes. However, these tests were only useful for checking the raw materials or the final product, and they did not offer an actual determination of the compounds that were present in an unknown perfume.

Taking into account the fact that many compounds are present in a perfume, the determination of the composition of an unknown perfume is not an easy task. As an example, fine fragrances can contain over 50 ingredients, and although the expertise of perfumers is sometimes useful, it is not enough to identify (and much less to quantify) all the compounds involved; powerful analytical techniques are also required. Separation techniques like chromatographic and related techniques are the most suitable for individual separation and determination of these compounds.

Bearing in mind that the compounds forming a perfume have a low boiling point, GC has been the most widely used technique in the perfume industry. In this sense, a perfume, after appropriate sample pretreatment, is analyzed using GC with a flame ionization detector (FID), and the Kovats index (KI) for each peak is experimentally determined. The identification is carried out by comparing the

experimentally determined KI with values kept in databases, although sometimes a composition is not completely resolved because there can be peaks with very similar KI values. Moreover, although the databases try to update frequently, new ingredients can be present, and the software library will not recognize these novel compounds. In these cases, an MS detector coupled with GC, instead of an FID, plays a crucial role since the chemical structure can be elucidated by studying the mass spectra of the compound. The use of GC-MS has been applied satisfactorily to analysis of different cosmetic products such as shampoos, creams, lotions, lipsticks, and face powder and to fine fragrances. In this sense, current databases besides the KI database also contain the mass spectra of compounds, making GC-MS a powerful analytical technique.

As has been mentioned above, recent EU norms require manufacturers to declare on the labels of cosmetic products the name of several ingredients that have been proven to be allergenic. However, no initiative has been taken yet to regulate the use of fragrance chemicals in cleaning products and other consumer products. The reason for this may be that knowledge about exposure estimates is not sufficient. **Figure 3** shows the feasibility of using GC-MS to determine 24 allergenic volatile chemicals in household and other consumer products.

On the other hand, perfumes contains compounds in very low concentrations that can be detected by the human nose, which can be extremely sensitive to these compounds. In these cases an FID is not appropriate because it is highly sensitive; however, an MS detector can settle the problem. Moreover, the MS detector can work in the selected ion-monitoring mode, making it more sensitive and selective.

**Figure 3** GC-MS chromatograms obtained for a standard mixture of potentially allergenic target compounds (upper) and for a commercial dishwasher product containing some of these compounds (bottom). 1, benzyl alcohol; 2, limonene; 3, linalool; 4, methyl heptin carbonate; 5, citronellal; 6, citral; 7, geraniol; 8, cinnamal; 9, hydroxycitronellal; 10, anisyl alcohol; 11, cinnamyl alcohol; 12, eugenol; 13, coumarin; 14, isoeugenol; 15, 3-methyl-4-(2,6,6-trimethyl-2-cyclohexen-1-yl)-3-buten-2-one; 16, 2-(4-*t*-butylbenzyl)propionaldehyde; 17, amyl cinnamal; 18, hydroxy-methylpentyl cyclohexenecarboxaldehyde; 19, farnesol; 20, benzyl benzoate; 21, hexyl cinnamaldehyde; 22, benzyl salicylate; 23, benzyl cinnamate. (Reproduced with permission from Rastogi SC (2002) *Survey of Chemical Compounds in Consumer Products, Survey No. 8: Contents of Selected Fragrance Materials in Cleaning Products and Other Consumer Products*. Copenhagen: Danish Environmental Protection Agency.)

The internal standard method is often used for quantitative requirements.

Other chromatographic techniques, like liquid chromatography (LC) and thin layer chromatography (TLC), have been less widely used in perfume analysis. Different compounds such as benzylideneacetone, cinnamyl alcohol, isoeugenol, cinnamyl anthranilate, cinnamaldehyde, bergapten, citropten, coumarin, 6-methyl coumarin, and saffrole have been determined using either LC or TLC.

Many of the compounds present in perfumes are chiral, and sometimes the chiral ratio of a mixture can affect the odor of the perfume since the olfactory

receptor in the human nose is protein based and thus enantiospecific. Chiral columns can achieve separation and quantification of the different enantiomers of a target compound.

Nowadays, electronic noses have an increasingly prominent role in the field of perfume analysis. These instruments are devices composed of an array of nonselective gas sensors that can act in a manner similar to that of real biological noses. In this way, after exposure to analyte vapors, the analyte molecules diffuse and pass over the detectors, producing characteristic signal patterns, which are conveniently processed using multivariate data analysis (principal

**Figure 4** Classification of seven cosmetic products according to odor pattern recognition obtained using an electronic nose and analyzing the data using PCA. (Reprinted with permission from Van Asten (2002) The importance of GC and GC-MS in perfume analysis. *Trends in Analytical Chemistry* 21: 698–708; © Elsevier.)

component analysis (PCA), partial least squares, artificial neuronal networks). Electronic noses should be able to provide a fingerprint for each odor without any information about chemical composition. In this context, they have been applied to the identification of different compounds. Another application of the electronic nose is differentiation between various commercial fine fragrances, as can be seen in Figure 4.

component analysis (PCA), partial least squares, artificial neuronal networks). Electronic noses should be able to provide a fingerprint for each odor without any information about chemical composition. In this context, they have been applied to the identification of different compounds. Another application of the electronic nose is differentiation between various commercial fine fragrances, as can be seen in Figure 4.

## Introduction

Atmospheric monitoring was very effective in the days of air pollution episodes (such as the London smog incident of 1952) for investigating acute effects of highly concentrated atmospheric pollutants on human health because the outdoor concentrations of air pollutants were related to personal exposure to the pollutants. In recent years, such air conditions have been improved in many cities, air pollution criteria have been established for the protection of

human health, and various programs have been implemented effectively for cutting down emission of airborne pollutants to maintain or attain the criteria set. On the other hand, indoor pollutant levels may originate from indoor sources such as home cooking, some types of home heating, tobacco smoking, and others. The concentrations of such compounds as sulfur dioxide (SO<sub>2</sub>), nitrogen oxides (NO<sub>x</sub>), formaldehyde, and carbon monoxide (CO) might frequently be higher indoors than outdoors. Outdoor concentration data are no longer primary indicators of personal exposure to pollutants in the living environment as these days urban dwellers might spend as much as 90% of their time indoors. Instruments and/or devices are thus essential for monitoring either residential or personal exposure to hazardous air pollutants, so that the effects of the pollutants on human health may be estimated in epidemiological surveys.

Personal samplers are those for continuously monitoring exposure of persons to hazardous air-borne substances in the living and/or occupational environment. These samplers are often used in surveys to measure personal exposure to air pollutants and thus to calculate subjects' doses from their respiration and living patterns. Personal samplers may be categorized as either active or passive.

Passive samplers consist of a film or cartridge containing a collection medium and a small holder with a clasp and utilize the principles of permeation or diffusion. They do not use a pump to draw air through the collection medium but are directly exposed to air by being worn on a person's shoulder or chest for short or longer periods. Average exposures can be calculated for the relevant period from the amount of gas absorbed on the sampler. This type of device is inexpensive, lightweight, and easy to handle and wear. It is useful for monitoring personal exposure to gaseous substances for periods from several days up to a month. However, because the gas collection rates are low, indication of hourly changes of exposure or peaks of concentration may not be possible using them. In addition, the samplers are not applicable to suspended particulate matter (SPM) monitoring.

In contrast, active samplers are designed to draw a large volume of air through a collection medium using an air pump. They can detect air pollutants sensitively so that hourly variations of the components or high-concentration peaks can be monitored, and they are also applicable to SPM monitoring. As active devices are much larger than passive samplers, it may be somewhat difficult for a person to always wear the samplers in the living and/or occupational environment. Accordingly, most active samplers

should be located where people live and work, so that exposures can be determined through knowledge of how long a person remains in the monitoring place.

The following sections describe active personal samplers in use and some that are anticipated in the near future.

## Requirements for Active Personal Samplers

### Collection Media and Samplers for Air Pollutants

Table 1 shows active samplers that have actually been used in the fields of industrial hygiene and air pollution analysis. Midget impingers and bubblers using absorptive solutions have been mainly used to monitor hazardous substances at occupational settings. Recently, filters impregnated with collecting agents and minicartridges packed with effective adsorbents have been used to sample air pollutants in ambient air or industrial emissions. These can be convenient to handle and useful as active personal samplers. In particular, Sep-Pak<sup>®</sup> cartridges packed with silica particles, silica particles chemically bonded with octadecylsilane (ODS), or a mixture of silica particles and magnesium oxide particles, are conveniently used to collect various air pollutants. A Sep-Pak<sup>®</sup> cartridge coated with a derivatization reagent is useful for monitoring reactive or unstable hazardous substances such as aldehydes, thiols, and amines. Annular denuders can be useful for separately sampling gas and particulate substances either indoors or outdoors.

It is said that an ideal personal sampler is one that can continuously record any sampling place, time, and exposure to substances in the living place of a person. It is important for active samplers to monitor hourly exposures to the substances and to detect the numbers of hours or days when the exposure exceeds given concentrations or exhibits high-concentration peaks. For this purpose, the samplers must be able to monitor hazardous substances sensitively over a long period, with subsequent rapid and simple analysis. Furthermore, they must be lightweight, small, safe, and rugged enough to be carried or worn by a person or placed in any living or occupational setting. They must be inexpensive and require little maintenance since a number of devices are required simultaneously in an epidemiological survey. Unfortunately, there are no such ideal samplers: the most suitable samplers should be selected and used according to the purpose of the survey and the environment monitored.

**Table 1** Portable samplers for monitoring air pollutants in the active sampling mode<sup>a</sup>

<i>Sampler</i>	<i>Typical substances</i>	<i>Description</i>
Impingers and bubblers	NO <sub>x</sub> , SO <sub>x</sub> , NH <sub>3</sub> , inorganic anions, organic vapours	Collect substances by bubbling a sample through an absorbent solution. Unsuitable as personal samplers
Filters	Particulate matter, inorganic anions, PAHs, heavy metals, asbestos, inorganic gases, organic vapors	Mainly collect particulate matter in gas or air sample. Ionic component could be determined by IC, PAHs by LC after purification of the sample, and heavy metals by PIXE or INAA
Impactors	Particulate matter, inorganic anions, heavy metals	Classify and collect particulate matter in different sizes
Solid adsorbent columns (charcoal, silica gel, Tenax GC, etc.)	Solvent vapors, hydrocarbons, halogenated carbons, pesticides	Collect substances by passing an air sample through a sampling column packed with an adsorbent and desorbed by heating or eluted with CS <sub>2</sub> followed by GC analysis
Minicartridges impregnated with collecting reagents	Low-molecular-mass aldehydes, amines, thiols, carboxylic acids, phenols, NO <sub>2</sub> , HNO <sub>3</sub> , NH <sub>3</sub> , SO <sub>2</sub> , pesticides	Collect substances by passing a sample through a cartridge. A reactive or unstable substance may be converted to a stable compound using a derivatization reagent followed by LC analysis. Many compounds may be determined by LC or IC. Pesticides may be determined by GC-MS in secondary ion monitoring mode
Denuders	NH <sub>3</sub> , NO <sub>2</sub> , HNO <sub>3</sub> , SO <sub>x</sub> , HCl, carboxylic acid vapors	Separately collect gaseous and particulate matter using a diffusion tube followed by a particulate collector. Ionic components may be determined by IC after extraction

<sup>a</sup> See text for abbreviations.

Substances sampled using a sampler are usually determined directly or after sample preparation using an instrumental analysis technique such as gas chromatography (GC), liquid chromatography (LC), ion chromatography (IC), gas chromatography-mass spectrometry (GC-MS), particle-induced X-ray emission analysis (PIXE), or instrumental neutron activation analysis (INAA), among others.

### Sampling Pumps

A portable small pump that draws air efficiently is essential for an active personal sampler. A suitable pump should be compatible with SPM samplers and gas samplers, though the performance required may differ somewhat for different samplers. The pump should be small and lightweight and should be able to draw air for long periods using either small batteries or a household power supply. Several commercially available diaphragm air pumps, operated with either batteries or household power supplies, can draw air at precise flow rates in the range 0.2–6.0 l min<sup>-1</sup>. A sampler, an air pump, a flow controller, and batteries may be integrated into a small sound-proof case so as to be easily carried or worn and to alleviate noise pollution. The system should be

operated for more than 8 h. A thermometer and hygrometer may be necessary if there is no other way to measure temperature and humidity at the sampling site.

## Applications

A few simple personal sampling systems are shown in **Figure 1** for sampling SPM and gaseous and/or vapor components. The use of active samplers is described in the following sections according to the air pollutants.

### SPM and Metal Elements in SPM

SPM is usually defined as comprising particles less than 10 µm in diameter suspended in the atmospheric environment. In particular, air particulates less than 2 µm in diameter, which mainly originate from such sources as incinerators, boilers, and automobiles, may reach deeply into human lungs during respiration and thus cause respiratory diseases. SPM can be also produced by photochemical reactions of gaseous substances in the atmosphere.

An SPM sampler should sample a substantial volume of air (~1000 l) to collect size-classified SPM to the sensitivity level of a chemical balance.

The sampling system is somewhat large and heavy compared with a gas sampling system. Sampling is usually made with two- to three-stage size classification using an impactor and filters with different pore sizes. **Figure 2A** shows an NBS model portable ambient aerosol sampler for SPM that classifies 15–7  $\mu\text{m}$  particulates using an impactor, 5–3  $\mu\text{m}$  particulates on a 6.8  $\mu\text{m}$  nuclear pore filter coated with Apiezon grease, and particles less than 3  $\mu\text{m}$  on a 3  $\mu\text{m}$  polytetrafluoroethylene (PTFE) fiber filter.

Another sampler for industrial hygiene applications removes particles larger than 10  $\mu\text{m}$  and collects

2–10  $\mu\text{m}$  particles with an impactor and particles less than 2  $\mu\text{m}$  on a glass fiber filter on a PTFE net support. Air is sampled at 2.5  $\text{l min}^{-1}$  for 8 h or more. The classified SPM samples are weighed separately using a chemical balance, and the average SPM concentration can be calculated during the sampling period.

A small SPM sampler has been developed by improving a  $\beta$ -ray attenuation mass monitor often used at monitoring stations (**Figure 2B**). A magnetic card with a 13 mm diameter filter is inserted into the sample holder. Air is sampled through a 7 mm diameter circle of the filter at 0.5–1.0  $\text{l min}^{-1}$  for 8–24 h. Particulates larger than 10  $\mu\text{m}$  can be removed using a preimpactor. The card is removed from the holder and the SPM concentration is measured using the  $\beta$ -ray absorption method at a laboratory and recorded on the magnetic card with other necessary information.

SPM samples can be subjected to direct determination of metallic elements at ultratrace levels using PIXE or INAA. If such analytical instruments are available in a laboratory, personal monitoring of metallic elements in SPM is possible for short or long periods.

**Figure 1** Personal sampling devices. (A) Personal sampler for particulate matter. (B) Personal sampler for gaseous or vapor compounds. (C) Personal sampler for placement at a living or occupational site. (Courtesy of Sibata Scientific Technology, Tokyo, Japan, used by permission.)

### Organic Vapors

There are many sources of emission of organic vapors, including petroleum refining, chemical, painting,

**Figure 2** SPM samplers. (A) NBS model sampler. (Reproduced with permission from Masuda S and Koichiro Takahashi (1990) *Aerosols: Science, Industry, Health & Environment: Proceedings of the Third International Aerosol Conference, Kyoto, Japan, 24–27 September 1990* set 2 Vols. Oxford: Pergamon Press.)

cleaning and printing processes, automobiles, gasoline stations, and others.

A 70 mm long  $\times$  4 mm inner diameter (ID) glass tube, packed with 100–200 mg of 20–40 mesh charcoal, silica gel, or a mixture of charcoal and silica gel and sealed by melting the tube ends, can be used as a personal sampler for organic solvent vapors and petroleum vapors in the living or occupational place (Figure 3A). Air is sampled at 0.5–1.5 l min<sup>-1</sup> through the cartridge after the tube ends are broken. For analysis, the packing is placed into a test tube and extracted with 5 ml of carbon disulfide in an ultrasonic bath. The solution is centrifuged and analyzed for organic components using GC.

### Low-Molecular Mass Aldehydes and Phenols

Low-molecular mass aldehydes and phenols known to be hazardous and/or odorous substances may be emitted from incinerators, chemical plants, baking finish plants, and automobiles. They may be produced as secondary products of organic air-borne pollutants

by photochemical reaction. They might even be emitted indoors from tobacco smoking and items of furniture or utensils made from plastic materials.

A sampler used for C<sub>1</sub>–C<sub>4</sub> aldehydes is a minicartidge packed with 55–105  $\mu$ m silica particles or 55–105  $\mu$ m ODS chemically bonded silica particles (Sep-Pak<sup>®</sup> Silica or Sep-Pak<sup>®</sup> C<sub>18</sub>) coated with 1.0 mg of 2,4-dinitrophenylhydrazine (DNPH) and 20 mg of phosphoric acid (Figure 3B). A 10–50 l volume of air is sampled through the cartridge at 0.2–1.5 l min<sup>-1</sup> for 0.5–12 h. The substances trapped are eluted with 2 ml of acetonitrile. The aldehydes are derivatized quantitatively with DNPH to stable hydrazones on the trap and/or in the elution media. The derivatization products are analyzed for the aldehydes using LC (Figure 4A). When 50 l of air is sampled, aldehydes can be detected down to the 0.2 ng l<sup>-1</sup> level. Sep-Pak<sup>®</sup> C<sub>18</sub> coated with 900  $\mu$ g of sodium hydroxide is used as a sampler for phenols. A 2–100 l volume of air is sampled at 0.2–1.0 l min<sup>-1</sup> through the cartridge. The adsorbed substances are eluted with 2 ml of methanol and derivatized at pH 11.5 by

LC conditions: 20 cm  $\times$  4.0 mm ID LiChrosorb RP-18 (5  $\mu$ m); mobile phase 50:5:45 (v/v) methanol–acetonitrile–water 1.0 ml min<sup>-1</sup>. Peaks: 1, ammonia; 2, methylamine 5.9 ng l<sup>-1</sup>; 3, ethylamine (below detection limit); 4, dimethylamine 7.5 ng l<sup>-1</sup>. (From Nishikawa Y and Kuwata K (1984) Liquid chromatographic determination of low molecular weight aliphatic amines in air via derivatization with 7-chloro-4-nitro-2,1,3-benzoxadiazole. *Analytical Chemistry* 56: 1790.)

adding 300  $\mu$ g of *p*-nitrobenzenediazonium tetrafluoroborate. The azo derivatives produced are assessed for the phenols using LC with ultraviolet (UV) detection. A large volume of the sample solution can be introduced into the LC column by using a minicolumn to detect the phenols at 0.01 ng l<sup>-1</sup> levels.

#### Low-Molecular Mass Alkylamines, Alkylthiols, and Fatty Acids

These compounds may be odorous substances produced by anaerobic decomposition of organic compounds containing nitrogen, oxygen, and/or sulfur. The vapors can be sampled in a manner similar way to that for the aldehydes using the following minicartridges (**Figure 3B**).

A Sep-Pak<sup>®</sup> C<sub>18</sub> cartridge coated with 900  $\mu$ g of phosphoric acid is used for sampling C<sub>1</sub>–C<sub>4</sub> alkyl primary and secondary amines. A 5–100 l volume of air is sampled through the cartridge at 0.8–1.2 l min<sup>-1</sup>. The trapped substances are eluted with 5 ml of methanol and derivatized by mixing with 4 mg of 7-chloro-4-nitro-1,2,3-benzoxadiazole (NBD-Cl) and 2 mg of potassium hydroxide. The

derivatization products are determined for the amines using LC (**Figure 4B**).

A Sep-Pak<sup>®</sup> Fluorisil (20 mm  $\times$  10 mm ID minicartridge packed with 0.14 g of 50–200  $\mu$ m silica particles and 0.76 g of 50–200  $\mu$ m magnesium oxide) is coated with 2 mg of NBD-Cl for sampling C<sub>1</sub>–C<sub>4</sub> alkylthiols. A 1–100 l volume of air is sampled at 0.8–1.2 l min<sup>-1</sup> through the cartridge. The trapped components are eluted with 2 ml of methanol. The derivatization may be completed by the catalytic effects of magnesium oxide in the methanol media. The derivatization products are assessed for the alkylthiols using LC with fluorescence detection.

Sep-Pak<sup>®</sup> C<sub>18</sub> coated with 300  $\mu$ g of sodium hydroxide is used for sampling C<sub>2</sub>–C<sub>4</sub> fatty acids. A 1–100 l volume of air is sampled at 0.5–1.5 l min<sup>-1</sup> through the cartridge. The adsorbed substances are eluted with 2 ml of acetonitrile and derivatized by mixing with 0.4 mg of 18 *p*-bromophenacylbromide and 0.04 mg of 18-crown-6-ether. The phenacyl derivatives produced under catalytic effect of the crown ether are assessed for the fatty acids using LC with UV absorbance detection.

Any of the methods described above can be used to detect the substances down to 0.1 ng l<sup>-1</sup> when 100 l of air is sampled.

#### Nitrogen Oxides, Sulfur Oxides, and Hydrochloric Acid

These compounds are mainly emitted from incinerators, boilers, and chemical plants. In particular, high levels of nitrogen oxides may often be detected indoors as they may arise from some types of home-heating stove, kitchens, and even tobacco smoking.

Various types of monitoring instruments are used for these gases at monitoring stations or at emission sources, but they may be difficult to use as personal samplers owing to their large size and high cost.

Minicartridge samplers have been developed so that the substances can be sensitively and simultaneously determined using IC. A Sep-Pak<sup>®</sup> C<sub>18</sub> cartridge impregnated with 600  $\mu$ g of triethanolamine and 600  $\mu$ g of potassium hydroxide may be convenient as a personal gas sampler for these components, while an absorption filter or a combined filter and annular denuder can be used for separate collection of the gas-phase and particulate-phase substances. A 10–100 l volume of air is sampled at 0.8–1.2 l min<sup>-1</sup> through the cartridge. The trapped ionic substances are eluted with 5 ml of an IC eluent and determined simultaneously using IC. **Figure 5** shows a chromatogram of ionic compounds from the atmosphere. The minicartridge can be used as a passive sampler after some modification.

**Figure 5** Ion chromatogram for determining ionic substances in the atmosphere. Active sampling volume 201 l;  $\text{NO}_2^-$  118 ng;  $\text{NO}_3^-$  72 ng;  $\text{SO}_3^{2-}$  22 ng;  $\text{SO}_4^{2-}$  47 ng. (From Nishikawa Y and Taguchi K (1987) Ion chromatographic determination of nitrogen dioxide and sulphur dioxide in the atmosphere using triethanolamine-potassium hydroxide-coated cartridges. *Journal of Chromatography* 396: 251.)

### Ammonia

Ammonia is mainly produced by anaerobic decomposition of nitrogen-containing organic compounds and is emitted into the atmosphere. It is the major nitrogen compound released on the surface of the earth. It is odorous and stimulative.

A minicartridge packed with a weak cation exchanger (Sep-Pak<sup>®</sup> ACCELL CM) has been used for sampling ammonia. A 1–100 l volume of air is sampled at 0.2–1.0 l min<sup>-1</sup> through the cartridge. The trapped substance is eluted with 2 ml of 0.02 mol l<sup>-1</sup> hydrogen chloride solution and determined using IC. The recovery of ammonia from the cartridge is 98% and the relative standard deviation ( $n = 6$ ) of the determined values is 2%. Gaseous ammonia and ammonium compounds can be sampled separately in combination with a small annular denuder coated with citric acid and a filter.

### Polynuclear Aromatic Hydrocarbons

Polynuclear aromatic hydrocarbons (PAHs) may be produced in the incineration of organic materials and may be adsorbed on particulate matter in the

atmosphere. They may be important factors in risk assessment, because some congeners such as benzo(a)pyrene may show high carcinogenicity.

The SPM sample, collected using the methods described above ( $\sim 1 \text{ m}^3$  of air sampled), is extracted with 4 ml of benzene–ethanol (3:1 v/v) in an ultrasonic bath for 10 min. A 2 ml volume of the sample is dried at 60°C by slowly flushing nitrogen over it, dissolved in 1 ml of hexane, and introduced into a Sep-Pak<sup>®</sup> Silica cartridge.

The cartridge is rinsed with 5 ml of hexane, and the PAHs are eluted with 4 ml of dichloromethane–*n*-hexane (50:50 v/v). The eluate is again dried in a similar way and dissolved in an LC eluent (acetonitrile–methanol–water (50:35:15 v/v), followed by reversed-phase LC with fluorescence detection. The PAHs are detectable at 0.1 ng m<sup>-3</sup> levels when 1 m<sup>3</sup> of air is sampled.

### Pesticides

A person might be exposed to pesticides at a golf course or in a garden or even indoors as well as in agricultural or forestry settings.

A minicartridge, such as a Sep-Pak<sup>®</sup> C<sub>18</sub> cartridge, may be convenient for personal monitoring. A volume of air up to 1000 l is sampled at 0.7 l min<sup>-1</sup> through the cartridge. The trapped components are eluted with 5 ml of hexane. The sample is mixed with 5–50 ng of [<sup>13</sup>C<sub>6</sub>]hexachlorobenzene as an internal standard and reduced to 0.1 ml by gently flushing nitrogen over it. A 2 µl volume of the sample is analyzed in the selected-ion monitoring mode using GC–MS. Pesticide components can be determined at 0.1 ng m<sup>-3</sup>.

## Basic Theory

Acute or chronic exposure to the thousands of minor components that can be present in the air we breathe may cause adverse health effects. Such exposure may occur in the workplace, home, or outdoor environment. Monitoring of these components is required to ensure compliance with recommended or regulated air quality standards. The preferred monitoring method would give a continuous and accurate measurement of instantaneous changes in the concentration of each harmful species present, in a manner that would model human exposure. The compromise most often applied in practice is to extract the components from a large volume (to provide sensitivity) of breathing zone air together with subsequent laboratory analysis (to provide selectivity).

In the 'active' method of extracting the gas and vapor components of air, a known volume is passed through an apparatus containing liquids in which the

components can dissolve, porous solids on which the components can be adsorbed, or liquids or solids containing chemicals with which the components can react. The total volume of air passed is metered by the pump, and both pump and extraction apparatus are placed appropriately about the person to obtain a representative sample. The pumps have been criticized as bulky, heavy, and noisy, and therefore an encumbrance to the wearer, and also as expensive.

An alternative method known as 'passive' or diffusive sampling, which does not require a pump or air mover, has gained popularity in recent years. Diffusive samplers operate by allowing the gas and vapor molecules to make their own way to the collection medium by diffusion along a carefully controlled path. The rate of movement, which is a function of the diffusion coefficient of the gas or vapor in air and the path geometry (Figure 1), can be derived from Fick's first law of diffusion:

$$W = -DA \frac{dc}{dx}$$

where  $W$  is the rate of mass transfer ( $\text{ng s}^{-1}$ ),  $D$  is the diffusion coefficient ( $\text{cm}^2 \text{s}^{-1}$ ),  $A$  is the cross-sectional area of the diffusion path ( $\text{cm}^2$ ), and  $dc/dx$  is the rate of change in concentration over the

## Basic Theory

Acute or chronic exposure to the thousands of minor components that can be present in the air we breathe may cause adverse health effects. Such exposure may occur in the workplace, home, or outdoor environment. Monitoring of these components is required to ensure compliance with recommended or regulated air quality standards. The preferred monitoring method would give a continuous and accurate measurement of instantaneous changes in the concentration of each harmful species present, in a manner that would model human exposure. The compromise most often applied in practice is to extract the components from a large volume (to provide sensitivity) of breathing zone air together with subsequent laboratory analysis (to provide selectivity).

In the 'active' method of extracting the gas and vapor components of air, a known volume is passed through an apparatus containing liquids in which the

components can dissolve, porous solids on which the components can be adsorbed, or liquids or solids containing chemicals with which the components can react. The total volume of air passed is metered by the pump, and both pump and extraction apparatus are placed appropriately about the person to obtain a representative sample. The pumps have been criticized as bulky, heavy, and noisy, and therefore an encumbrance to the wearer, and also as expensive.

An alternative method known as 'passive' or diffusive sampling, which does not require a pump or air mover, has gained popularity in recent years. Diffusive samplers operate by allowing the gas and vapor molecules to make their own way to the collection medium by diffusion along a carefully controlled path. The rate of movement, which is a function of the diffusion coefficient of the gas or vapor in air and the path geometry (Figure 1), can be derived from Fick's first law of diffusion:

$$W = -DA \frac{dc}{dx}$$

where  $W$  is the rate of mass transfer ( $\text{ng s}^{-1}$ ),  $D$  is the diffusion coefficient ( $\text{cm}^2 \text{s}^{-1}$ ),  $A$  is the cross-sectional area of the diffusion path ( $\text{cm}^2$ ), and  $dc/dx$  is the rate of change in concentration over the

**Figure 1** The geometry of the diffusion path.

diffusion path ( $\text{ng cm}^{-3} \text{ cm}^{-1}$ ). If the diffusion path is considered to be the length  $L$  (cm) of the air gap in the sampler, and the concentration at the sorbent is considered to be negligible (the so-called ‘zero-sink’ condition), then the mass  $M$  (ng) adsorbed by the sampler from an atmosphere of concentration  $C$  ( $\text{ng cm}^{-3}$ ) in time  $t$  (s) is given by

$$M = D \frac{A}{L} C t$$

The uptake rate of the sampler is given by the expression  $D(A/L)$ , which has units ( $\text{cm}^3 \text{ s}^{-1}$ ) dimensionally equivalent to a volume flow rate. The geometry of the sampler is known from measurement, but very few diffusion coefficients have been measured. They can be calculated, assuming certain rules for calculating molecular size, but these need to be correlated with experimental determinations of uptake rates from atmospheres of known concentration. This gives a correction factor that depends on the chemical makeup of the molecule, and which can then be used to adjust the calculated values of other, similar molecules.

Fick’s second law of diffusion can be used to derive an expression for the time required to set up steady-state conditions within the sampler once the diffusion path is exposed to an ambient vapor concentration, which can also be applied to the behavior of molecules within the diffusion path after the sampler is closed. The time taken for a molecule to traverse the diffusion path is given by  $L^2/D$ , which for benzene is 11 s when the diffusion path is 1 cm. When diffusive samplers, especially those where the diffusion path is long, are used to sample for short periods of time, these time-related effects can be significant sources of error. Sampling transient and rapidly fluctuating peaks of concentration provides another source of time-related errors. In this case, however, the finite bounds on the height and width of real peaks are a finite bound on the maximum error. These types of errors have been carefully considered and discussed in the literature. Experimental validations often provide evidence

of a higher uptake rate during short ( $<15$  min) exposure periods.

The diffusion coefficient is affected by temperature and pressure, but so too is the concentration. The mass collected by the sampler is therefore proportional to the square root of the absolute temperature and independent of pressure. The temperature effect should be less than  $0.2\% ^\circ\text{C}^{-1}$ , and is normally ignored, since the variation from the measured uptake rate should be less than 5% from room temperature to  $0^\circ\text{C}$  and from room temperature to  $40^\circ\text{C}$ .

Results from diffusive sampling are often provided in terms of parts per million by volume ppm under the sampling site conditions of temperature and pressure. When the limit values to which these concentrations will be compared are stated in the same terms, then the statements in the preceding paragraph hold true. However, the origin of many limit values used around the world are the TLV<sup>®</sup>s of the American Conference of Governmental Industrial Hygienists (ACGIH). These values are stated in units of mass per unit volume (e.g.,  $\text{mg m}^{-3}$ ), while TLVs for gases and vapors are also stated in units of ppm at NTP (or  $25^\circ\text{C}$ , 1 atm, in the USA). In order to compare a result to these values, the diffusion coefficient is corrected for the difference between NTP and the sampling site pressure and temperature, but the concentration is not. This procedure is to be used, for example, for comparing results to the US Occupational Safety and Health Administration (OSHA) permissible exposure limits (PELs). The potential effect of this calculation is significant and could be as much as 20%, given extremes of temperatures or altitude.

The diffusion pathlength is affected by ambient air movement. Strong air currents around the face of the sampler may cause turbulent effects within the diffusion gap, effectively reducing the diffusion path, while weak air currents may not be sufficient to replenish molecules that have migrated to the sampler, effectively extending the diffusion path beyond the sampler face. The diffusion pathlength is also affected if the concentration at the sorbent face is not zero; therefore, the two principal factors that need to be considered in the application of a diffusive sampler are the geometry of the sampler and the type of sorbent. These two factors have the greatest influence on sampler performance.

## Types of Sampler

### ‘Tubes’ versus ‘Badges’

The diffusion path to the sorbent can take many forms. The simplest version is an open tube. This was

the construction used for sampling nitrogen dioxide in the original investigations into diffusive sampling by Palmes, and it is still in use today. An open tube may be affected by air currents disturbing the still air conditions required in the diffusion path, so that tubes without a windscreen must be long with respect to their diameter, with a ratio in excess of 3:1. Unfortunately, a long diffusion path results in a lower uptake rate (typically  $\sim 0.3\text{--}3.0\text{ ml min}^{-1}$ ) and much increased response time, reducing the application for short-term exposure determinations. However, the low uptake rate also reduces the possibility of starvation at the open face, so that the tube design can be used in areas of reduced air movement; and the low uptake rate also decreases the possibility of sorbent saturation, so that much longer sampling periods, of the order of weeks or months, can be used.

One major advantage of a tube design is the potential for gas-flushing organic vapors from open-ended tubes in a thermal desorption system directly into an analytical device, usually a gas chromatograph with flame-ionization detector or mass spectrometer. An example is shown in Figure 2 (second from left). The convenience of this procedure makes it very popular, although the analysis is limited to a single shot.

A second form of construction is to use a number of shorter, narrower tubes, which at the extreme can be reduced to a thin, porous membrane. The short

diffusion path results in a faster response time, and also combines with the larger overall sorbent surface area to give much higher uptake rates. This situation is better for short-term sampling, but may lead to the possibility of overloading at high exposure doses. The higher uptake rate of these samplers (typically  $6\text{--}60\text{ ml min}^{-1}$ ) requires more air movement, normally at least  $10\text{--}20\text{ cm s}^{-1}$ , around the open face in order to prevent starvation. With personal monitoring, natural movements of the body are assumed to give rise to sufficient air movement, but problems can still arise where workers are in sedentary occupations or where their movements are severely restricted. While badge-type samplers are not prone to effects from air movement parallel to the face, since each individual diffusion element normally has a length-to-diameter ratio of at least 3:1, perpendicular air movement has been shown to be able to cause a 'scooping' effect if there is communication between the bases of the tubes. A windscreen made from a porous membrane, sited above or below the diffusion path, will prevent this. Examples of these 'badge-type' samplers are shown in Figure 2 (third, fourth, and fifth from left).

### The Choice of Sorbent

The best choice of sorbent is one that will react with the component of interest to produce a nonvolatile, easily analyzable derivative. Indeed, if the derivative is colored, the analysis can be of extremely low cost and can be performed onsite. This was a very exciting possibility that was investigated at an early stage in the development of diffusive samplers, and a number of samplers have been produced commercially. Many use water-soluble reagents in aqueous solution as the sorbent, held in place by hydrophobic or high-water-content polymer membranes. These membranes can act as the control over mass transfer, or they can be used together with a diffusive air gap. Analysis requires an inexpensive spectrophotometer. Reagents coated onto an inert substrate can also be used and can be analyzed by reflectance spectrophotometry, although cheap and accurate field instrumentation has only recently become available.

There are a number of drawbacks to this technique, such that it is generally employed for certain specific gases and vapors. The reagents and products must be stable, and the analysis must be sensitive and free from interference. Finally, the method must satisfy stringent precision and accuracy requirements for use in hygiene investigations where compliance with government regulated exposure guidelines must be demonstrated; otherwise, the technique still has value in screening tests. Greater precision and accuracy are normally attainable with a laboratory

**Figure 2** Types of diffusive samplers. From the left: a colorimetric length-of-stain sampler; a tube-type sampler for thermal desorption; a badge-type sampler with multiple channels and no windscreen, containing a removable sorbent pad for solvent desorption; a badge-type sampler with multiple channels and an internal windscreen, containing granular sorbent for *in situ* solvent desorption; a badge-type sampler with an external windscreen, behind which is an open diffusion path, and containing a sorbent pad for *in situ* solvent desorption.

analytical technique, such as liquid chromatography (LC), ion chromatography, or polarography. The gases and vapors most frequently applicable to this method are inorganic compounds; for example, chlorine, ammonia, sulfur dioxide, and hydrofluoric acid. Formaldehyde is the compound most frequently determined by this method.

The use of colorimetric detector tubes in a diffusive mode is an extension of this type of method. In this case, reaction with a substrate contained in a tube produces a color change, the extent of which is related to the applied dose. In addition to the drawbacks of colorimetric analysis mentioned above, there is a further inaccuracy involved in reading the extent of the color change, which is complicated by being nonlinear with respect to exposure dose (concentration multiplied by time). An example of this type of sampler is shown in **Figure 2** (far left).

The preferred technique for sampling organic vapors is collection on a porous sorbent by the van der Waals forces of adsorption (particularly the London dispersion force), with later desorption and instrumental analysis. The rate of adsorption at the sorbent surface is extremely fast and is not normally considered a rate-controlling step, and the adsorption equilibrium is normally shifted far enough in the direction of the adsorbed phase that the concentration at the sorbent surface can be regarded as insignificant. All molecules that arrive at the surface are therefore adsorbed. The adsorbed vapors are extracted from the sorbent by means of a solvent or heat, and analysis is normally carried out by gas chromatography (GC), or less often by LC.

Sorbents differ in their affinity for different vapors, and sometimes this will cause a particular sorbent-vapor combination to deviate from the ideal behavior described above. Weak sorbent-sorbate interactions can cause the concentration of the vapor to be significantly greater than zero at the sorbent surface, and to increase with increasing exposure dose. This will result in saturation where the sorbent is a thin layer, as in badge-type samplers, or a progressive increase in the diffusion path through the sorbent where it is disposed in a thick bed as in many tube-type samplers. Both effects produce the same result, a progressive reduction in the sampling rate with time, leading to an underestimation of the applied concentration. In addition, if the concentration at the open face of the sampler is reduced to zero, adsorbed sample can re-equilibrate with the vapor phase and diffuse back out of the sampler. This is known as reverse diffusion, and it too results in an underestimate of the true exposure dose.

In general, the sorbents used in the tube-type samplers for thermal desorption tend to be porous

aromatic polymers, or graphitized carbon blacks that adsorb little water to interfere with the GC analysis, and where the van der Waals forces of adsorption are not so strong as to require excessive temperatures for desorption. Because of these weak interactions, saturation and reverse diffusion must be expected and guarded against in the method evaluation. Carbon and zeolite molecular sieves have been used to adsorb the most volatile molecules, but water adsorption makes analysis by thermal desorption more complex.

Conversely, the preferred sorbent for the badge-type samplers is activated charcoal, which has a greater capacity for organic vapors. Saturation and reverse diffusion are less likely to occur except with the most volatile compounds, e.g., acetone or methylene chloride. One method of counteracting these effects is by means of two layers of sorbent, the second acting as a backup analogous to the backup section in pumped sorbent sample tubes. Unfortunately, research has shown that reverse diffusion takes place at the same time as migration to the second layer, and sample loss is slowed but not avoided completely. Extra sorbent sections, therefore, are not a completely reliable guarantee of sampling accuracy.

Desorption of these samplers is by means of a solvent, which often can be added directly to the closed sampler. Solvent desorption of active charcoal is not usually as efficient as thermal desorption with porous polymers for a number of reasons. First, desorption efficiency depends on the partition equilibrium of the compound between the solvent and the charcoal. Second, a certain proportion of the sample may be lost irretrievably within bottle-necked pores, by reaction with surface-active sites, or by partition into an aqueous phase resulting from the simultaneous desorption of adsorbed water. This latter can be retrieved by desorption using a more polar solvent mixture. In general, these losses are somewhat balanced by loss of the solvent through adsorption on the charcoal. The resulting recovery can range from 80% to 110% of the applied dose, and this needs to be carefully characterized. Recoveries of polar and reactive compounds tend to fall further at lower loadings. Losses may also occur during storage of the sampler after use, and this too must be carefully characterized. Porous polymers are not immune to sample losses during thermal desorption or storage, although it occurs less often. Perhaps the biggest drawback of solvent desorption is the reduced analytical sensitivity caused by the solvent dilution of the sample. Thermal desorption without focusing also results in sample dilution because the amount of carrier gas required for sample desorption and correction cannot all be passed into a capillary GC column.

A splitter valve may be required to dispose off much of the sample.

For most general purposes the choice of tube versus badge revolves practically around the preferred desorption technique, provided the correct sorbent is selected for the tube-type sampler. Tenax<sup>®</sup> TA is often used, even though it has a small surface area and low capacity for volatile compounds. Porapak N is sometimes employed for polar compounds, but the capacity is also quite low and is compromised by high relative humidities. Chromosorb<sup>®</sup> 106 is a good all-round medium, with a surface area  $\sim 700\text{--}800\text{ m}^2\text{ g}^{-1}$  and hydrophobic character, but there is a gradually increasing background caused by slow polymer degradation or trapping of adsorbed material that is released on subsequent uses. This can be a problem in sampling very low concentrations, such as in indoor air-quality surveys.

One important consideration is the possibility of reuse of thermal desorption tubes, since they are cleaned in the desorption step. Charcoal badge-type samplers are of single-use nature but cheaper. Solvent desorption also allows multiple analyses from a single sample to give greater accuracy.

## Validation of the Sampling Method

The precision and accuracy of any measurement method must fall within acceptable bounds. Precision is normally denoted by the bias, or deviation of an average measurement from the 'true' measurement as recorded by an unbiased reference method. Accuracy is normally denoted by the spread of results about the mean, and is defined as twice the pooled coefficient of variation of the method. According to the National Institute of Occupational Safety and Health (NIOSH) in the United States, a method is acceptable if 95% of the results fall within 25% of twice the pooled coefficient of variation plus the absolute bias (regardless of sign). A lower level of overall accuracy for measurements taken at concentrations below regulated limit values is often acceptable and the Committee for European Normalization (CEN) suggests a relaxation to 50% at concentrations below one-half the limit value, or over the full range if the measurements are made for screening purposes only.

Experimental tests are required to confirm acceptable sampler performance. NIOSH, and the Health and Safety Executive in the United Kingdom, have published diffusive sampler evaluation protocols that cover the effects of exposure, time, concentration, desorption efficiency, storage stability, reverse diffusion, temperature, humidity, presence of interfering compounds, face velocity, and orientation. Many of

these factors are varied together in a multifactorial study to determine the possibility of interactions. Precision and accuracy are determined from the combined results of these experiments. A working group of CEN is currently drafting a similar protocol. All of these protocols require laboratory exposure studies in atmospheres of closely controlled composition. The expense of producing good-quality atmosphere generation rigs together with the time and costs of running the full set of experiments (equivalent to about three technician-months per validated compound) have been a barrier to the widespread adoption of these protocols. A useful suggestion for reducing the number of required experiments is the concept of bilevel validation, which involves performing the full set of validation tests on one member of a homologous series, together with a reduced set of tests on the higher members of the series if the first member passes. This allows the validation of about one series (e.g., aliphatic hydrocarbons, aromatic hydrocarbons, chlorinated aliphatic hydrocarbons, ketones, acrylates, aliphatic alcohols, etc.) per year.

In addition to laboratory tests, field trials are recommended or required by the protocols. Two types of field trials are suggested, one being a large set of diffusive samplers and reference methods arranged in a static array, the other consisting of a number of pairs of diffusive samplers and reference methods as static or personal monitors. The results of these tests require cautious analysis to be sure they are effective. For instance, the effects of environmental conditions on the reference methods need to be known and accounted for, and the statistical tests most appropriate to the situation must be applied. It is unfortunate that to date very few samplers have been evaluated according to these protocols, since only through such tests can confidence in the measurements be assured. Table 1 gives a summary of the compounds validated using one particular badge-type sampler containing one or another of two different sorbents. All of the compounds tested according to the full protocol had acceptable overall accuracies. It is normally the case that well-designed diffusive samplers have precision and accuracy characteristics comparable to other accepted methods.

## Active versus Passive Sampling

As mentioned in the introduction, the chief drawback to the pumped system has been the pump itself, which is normally described as bulky, heavy, noisy, and expensive, and which requires frequent calibration and periodic maintenance and repair. However, manufacturers have addressed these criticisms over

**Table 1** Compounds validated using the SKC Inc 575 series badge-type sampler with (A) charcoal and (B) Anasorb<sup>®</sup> 747 sorbents

<sup>a</sup>Full validation according to NIOSH protocol, all others partially validated according to bi-level validation theory.

the previous decade. Today's models are smaller, lighter, and quieter, and miniaturized versions with total volumes of 50 cm<sup>3</sup> or less will be available in the near future. Onboard computer calibration is possible, and pumps are generally of more rugged construction than before. In addition, the cost of a pump is spread over a very large number of individual samples, and the major cost per sample is the analysis. A pump provides the advantage of a series of samples, such as in a backup sorbent layer, to detect breakthrough from the primary collection layer. To ensure the same safety factor in diffusive sampling, two samplers with different uptake rates can be employed, the ratio between the collected samples being the critical factor in proving a good sample. One definite advantage of the diffusive sampler is that it can be left unattended during operation, while the operation of the sampling pumps must be checked regularly during use. In addition, it is not necessary to account for pump error.

Often the cost factor is represented as a contest between diffusive samplers with thermal desorption

on the one hand and pumped samplers with solvent desorption on the other. This is not quite an accurate picture, since there are plenty of examples of alternative techniques; that is, diffusive sampling with solvent extraction and pumped sampling with thermal desorption. Both thermal and solvent desorption can be automated and run overnight. The tubes used in pumped sample trains are less expensive than any diffusive sampler, but they are of single-use type, unlike thermal desorption tubes. Overall, the costs are probably not very different, and the differences are minimized further when including other costs of the sampling exercise, such as the costs of taking the sample, the analysis, and the interpretation of the result.

One very important difference between pumped and diffusive sampling occurs when aerosols or dusts containing the compounds of interest are present. Pumps are able to draw these species into an adsorbent tube or impinger, where the compounds of interest will be collected, although not necessarily with 100% efficiency. Diffusive samplers cannot collect anything other than gases or vapors, but if dust or aerosol becomes attached to the face it can outgas volatile components even after the sampler is closed. A heavy loading of dust, grease, or condensation on the sampler face can block the diffusive uptake, and tears or perforations of delicate membranes can also affect the uptake rate. Many problems associated with the use of diffusive samplers have been traced to careless handling and contamination.

Finally, it is important to remember that the sampling rate of a diffusive sampler is different for individual chemicals and it is not possible to provide uptake rates for complex mixtures, and that the sampling rate is fixed, while that of a pump can be adjusted up to 1000 ml min<sup>-1</sup> or more for additional sensitivity.

## Permeation Samplers

Diffusion through materials other than air is possible, and a number of polymer materials have been tried, either alone, or in combination with an air gap. It is important to distinguish these membranes from those that are porous, where the primary control of mass transfer is still diffusion in air. Diffusion through polymers is much slower than through air and is normally referred to as permeation. Permeation samplers have advantages (for instance, organic vapors may permeate through a hydrophobic membrane while interfering water vapor does not) but also have disadvantages, mainly as a result of variations in the thickness or composition of the membranes, and the lower uptake rate.

## Introduction

An exhaustive overview on pesticides should include aspects referring to their synthesis and formulation (and related quality control features), mechanisms of action, degradation and/or metabolism patterns, and their impact on environment and living organisms, including on human health. Analytical chemistry is directly involved in all these domains and takes into account at least three major difficulties: extreme diversity of the target compounds, increased sample matrix complexity, and imposed levels of detectability, which are continuously decreasing. The article starts by defining pesticides and related topics together with their classification criteria and class exemplification. Thus, attention is focused on the

analytical contributions to the topic. The sample preparation approach reviews analytical techniques involved in the isolation, concentration, and derivatization of pesticides and pesticide residues from real samples of different origin (environmental, food, clinical, forensic, etc.). Recent developments such as focused microwaves Soxhlet extraction, solid-phase extraction and microextraction on immunosorbents, shielded materials and molecular imprints, stir-bar sorptive extraction, supported liquid membrane extraction, and supercritical fluid and pressurized fluid extractions are discussed. The main achievements related to pesticide separation by means of thin layer, gas, liquid, supercritical fluid, micellar electrokinetic, and capillary electro-driven chromatographic methods are also discussed. Special emphasis is given to mass spectrometric detection for its inherent selectivity and high sensitivity. In some circumstances, other analytical methods such as spectrometric, immunochemical, and electrometric (including bio- and immunosensors) methods can be successfully used for pesticide analysis. Due to the complexity of the subject, more often only recent advances have been detailed at some length.

## Introduction

The concept of pH is one of the most fundamental in chemistry, but has a broad significance in many other disciplines such as biochemistry, biology, physics, medicine, agriculture, environmental pollution, and is important in numerous practical fields, especially in chemical industry, environmental protection, food production, and others. This article discusses the basic definitions of pH, its effect on some fundamental chemical reactions of importance in analytical chemistry. Although the concept of pH is mainly used for aqueous solutions its extension to other solvents is mentioned, as well as the main methods of pH evaluation.

## General Concept

The concept of pH arose from the idea that the acidity of a medium was related to the concentration of hydrogen ions. This has been shown to be valid for water and water-like media, where the species responsible for acidity is the ion assumed by convention to be  $H^+$ . In fact, this is a solvated ion and the number of solvating molecules of the solvent is not strictly defined, but for dilute solutions it is assumed to be constant. Nevertheless, this solvated ion is sometimes shown as  $H_3O^+$  in water,  $CH_3OH_2^+$  in methanol,  $CH_3COOH_2^+$  in acetic acid, etc.

The first definition of pH, given by S P L Sørensen in 1909, defined pH as the negative logarithm of the hydrogen ion concentration:

$$pH = -\log_{10}[H^+] \quad [1]$$

The introduction of the concept of activity ( $a_H$ ) as a driving force in chemical and biochemical processes has modified this definition such that

$$pH = -\log_{10} a_H = -\log_{10}(\gamma_{m,H} m_H) \quad [2]$$

where  $\gamma_{m,H}$  is the single molal activity coefficient of the hydrogen ion and  $m_H$  is the molality of the hydrogen ion. As formally the logarithmic term is dimensionless, the correct full expression should be

$$pH = -\log_{10}(\gamma_{m,H} m_H / m^0) \quad [3]$$

where  $m^0$  is an arbitrary constant, representing the standard state condition, numerically equal to

$1 \text{ mol kg}^{-1}$ . For most analytical purposes, this pH scale is equivalent to the scale based on molarity, where

$$pH = -\log_{10}(c_H \gamma_{c,H} / c^0) \quad [4]$$

where  $c_H$  is the molar concentration, expressed in  $\text{mol dm}^{-3}$  or  $\text{mol l}^{-1}$ , and  $\gamma_{c,H}$  is the molar activity coefficient. The difference between the two scales depends on the density of water; at 298.15 K this difference is  $\sim 0.001$  pH. As in most practical applications the uncertainty of pH measurement is usually  $< 0.01$  pH, such a difference is insignificant. The definitions given above are only notational definitions because it is not possible to measure single ion ( $H^+$ ) activity.

## Operational Definition

For practical purposes, pH is defined by measuring the difference between the electromotive forces of two cells, both of which have identical indicator electrodes and identical reference electrodes. One of the cells contains the standard reference solution (S) and the other cell contains the solution whose pH is to be determined (X). Denoting the corresponding electromotive forces as  $E(S)$  and  $E(X)$ , and the pH values as  $pH(S)$  and  $pH(X)$ , the pH value of the solution X is defined as

$$pH(X) = pH(S) + \frac{F[E(S) - E(X)]}{RT \ln 10} \quad [5]$$

where  $R$ ,  $T$ , and  $F$  are the gas constant, the thermodynamic temperature, and the Faraday constant, respectively. Hydrogen electrodes are generally used as the indicator electrodes in fundamental studies, but in practical measurements they can be replaced by any hydrogen-ion responsive electrode that works properly in the pH range studied. Among them mostly are used pH-sensitive glass electrodes. The reference electrode is connected through a potassium chloride bridge, which has KCl concentration of not less than  $3.5 \text{ mol kg}^{-1}$ .

The pH scale is usually based on primary buffer solutions (PS). A number of substances have been chosen as primary pH standards and their pH values are tabulated in Table 1. Their pH values have been accurately determined using a cell without liquid junction potential composed of the standard hydrogen electrode and a silver–silver chloride electrode

**Table 1** Values of pH(PS) for primary standard reference solutions at 25°C

Standard reference solution	pH
0.0341 mol kg <sup>-1</sup> potassium hydrogen tartrate	3.557
0.05 mol kg <sup>-1</sup> potassium dihydrogen citrate	3.776
0.05 mol kg <sup>-1</sup> potassium hydrogen phthalate	4.005
0.025 mol kg <sup>-1</sup> disodium hydrogenphosphate + 0.025 mol kg <sup>-1</sup> potassium dihydrogenphosphate	6.865
0.03043 mol kg <sup>-1</sup> disodium hydrogenphosphate + 0.008695 mol kg <sup>-1</sup> potassium dihydrogenphosphate	7.413
0.01 mol kg <sup>-1</sup> sodium tetraborate	9.180
0.025 mol kg <sup>-1</sup> sodium hydrogencarbonate + 0.025 mol kg <sup>-1</sup> disodium carbonate	10.012

Knowing the standard potential of the Ag–AgCl electrode, and the mean ion activity coefficient  $\gamma_{\pm}$  of 0.01 mol kg<sup>-1</sup> HCl from independent measurements the pH(PS) can be calculated as

$$\text{pH(PS)} = \left[ -\log_{10} \left( \frac{m_{\text{H}^+} \gamma_{\text{m,H}^+} \gamma_{\text{m,Cl}}}{m^0} \right) \right] + \log_{10} \gamma_{\text{Cl}} \quad [6]$$

where  $\gamma_{\text{Cl}}$  is obtained from the Bates–Guggenheim convention. The primary buffer solutions should be characterized by large buffer capacity, small temperature coefficient, small residual liquid junction potential, ionic strength  $\leq 0.1$  mol kg<sup>-1</sup>, and must have a certificate of the national metrological institute. The best results (uncertainty  $\pm 0.002$  pH) are obtained when the standard used as reference solution is similar (in terms of pH, composition, and ionic strength) to the solution being measured. Measurements within the pH range 3–10 can have an uncertainty of pH measurements  $< 0.02$  pH.

At constant ionic strength the activity coefficients may be assumed to be constant and therefore the difference between the activity  $\text{pH} = -\log_{10}(c_{\text{H}^+} \gamma_{\text{c,H}}/c^0)$  and concentration  $\text{pH}_c = -\log_{10}(c_{\text{H}^+}/c^0)$  is constant. If the standardization is carried out not by standard buffer solutions but by using solutions containing known hydrogen ion concentration, e.g., dilute HClO<sub>4</sub>, then measurements of the electromotive force allow the determination of  $\text{pH}_c$ , assuming that all solutions have the same ionic strength. Such a procedure is used in the study of protonation or complexation equilibria.

## Influence of pH on Chemical Equilibria

### Simple Protolytic Equilibria

pH is the parameter most often measured in chemistry, particularly in analytical chemistry. This is

**Figure 1** Distribution diagram (mole fraction versus pH) for formic acid ( $\text{p}K_a = 3.65$ ).

because the pH influences the position of chemical equilibrium of the majority of chemical reactions in aqueous solutions, and this can also be extended to other media. In several instances pH also influences the reaction kinetics, changing the rate and acting as a catalyst.

The simplest case involves the equilibrium of an acid–base reaction (in the Brønsted–Lowry sense). In typical acid–base titrations, the pH value is the analytical signal observed during the titration, but knowledge of the pH is essential for understanding the process and for choosing the optimal conditions for endpoint evaluation. The equilibrium of the reaction  $\text{HA} \rightleftharpoons \text{H}^+ + \text{A}^-$  is determined by the values of the acid dissociation constant,  $K_a = [\text{H}^+][\text{A}^-]/[\text{HA}]$  or the protonation constant  $K_H = [\text{HA}]/[\text{H}^+][\text{A}^-]$ . The influence of pH on the position of the equilibrium can be shown graphically by means of a mole fraction versus pH diagram (Figure 1), or by a plot of log concentration of a given species versus pH (Figure 2). Such diagrams are useful in predicting the pH at the endpoint of a titration,  $\text{pH}_{\text{end}}$ .

### Complex Equilibria

The concept of side reaction coefficients, introduced by A. Ringbom, is useful in describing the effect of pH on various equilibria. These coefficients combine the total (analytical) concentration,  $[\text{X}']$ , of the species of interest, with the concentration of its form  $[\text{X}]$ , which undergoes reaction. For example, for ethylenediaminetetraacetic acid (EDTA) the reacted form is the  $\text{EDTA}^{4-}$  anion, but the total concentration also includes all protonated forms. Thus, the side reaction coefficient,  $\alpha_{\text{EDTA(H)}}$ , is given by

$$\begin{aligned} \alpha_{\text{EDTA(H)}} &= [\text{EDTA}']/[\text{EDTA}] \\ &= 1 + K_{\text{H1}}[\text{H}^+] + K_{\text{H2}}K_{\text{H1}}[\text{H}^+]^2 \\ &\quad + K_{\text{H3}}K_{\text{H2}}K_{\text{H1}}[\text{H}^+]^3 \\ &\quad + K_{\text{H4}}K_{\text{H3}}K_{\text{H2}}K_{\text{H1}}[\text{H}^+]^4 \end{aligned} \quad [7]$$

**Figure 2** Logarithmic diagram for the formic acid–formate ion system for total concentration  $C = 0.1 \text{ mol l}^{-1}$ .

**Figure 3** Dependence of side-reaction coefficients, as  $\log \alpha$ , on pH for some bases (EDTA, anion of ethylenediaminetetraacetic acid; NTA, anion of nitrilotriacetic acid).

For various common ligands used in analytical chemistry, such side reaction coefficients can be presented graphically (**Figure 3**).

A similar procedure can be used in the case of such acids (according to the Brønsted–Lowry theory) as metal ions forming hydroxy complexes at elevated pH. Considering the reaction

as acid dissociation, the coefficient  $\alpha$  can be written as

$$\alpha_{M(OH)} = [M]/[M'] \\ = 1 + K_{Hn}[H^+] + K_{Hn}K_{H(n-1)}[H^+]^2 + \dots \quad [8]$$

or considering this reaction as the formation of hydroxo complexes with successive stability

constants  $K_1$ ,  $K_2$ , etc. of metal– $OH^-$  complexes:

$$\alpha_{M(OH)} = [M']/[M] \\ = 1 + K_1[OH^-] + K_1K_2[OH^-]^2 + \dots \quad [9]$$

The functions of  $\log \alpha_{M(OH)}$  versus pH are tabulated for a number of ions in **Table 2** and are shown graphically for some typical metal ions in **Figure 4**. The accuracy of such presentation is not very high. The accuracy of the calculations is also limited because of the dependence of equilibrium constants on the ionic strength and temperature, the discrepancies between data presented by different authors, and in particular because of the uncertainties about data in the range where polynuclear species may be formed. Nevertheless, in many analytical predictions and calculations such approach is very useful.

The pH value influences the solubility of precipitates of hydroxides of metals, for which the coefficient  $\alpha$  is  $>1$ . Using the concept of side reaction coefficients the conditional solubility products,  $K'_{s0}$ , can be calculated:

$$K'_{s0} = K_{s0}/\alpha_{M(OH)} \quad [10]$$

The  $\alpha_{M(OH)}$  coefficients should take into account the formation of polynuclear species.

The solubility of hydroxides can be also expressed in terms of the dependence of the total concentration of the soluble species of metal ion  $[M']$  on pH (**Figure 5**):

$$[M'] = K_{s0}/\alpha_{M(OH)}[OH^-]^n \quad [11]$$

For the salts of weak acids this equation can be extended by additionally taking into account the  $\alpha$  coefficient of the anion. Thus,

$$K'_{s0} = K_{s0}/\alpha_{M(OH)}\alpha_{L(H)} \quad [12]$$

Diagrams for several insoluble systems are shown in **Figure 6**.

The concept of conditional stability constants can also be applied to complexation reactions. The constant can be evaluated in the same way as shown in eqn [12] only instead of solubility products the complex stability constants,  $\beta'_{ML}$ , are considered. Thus,

$$\beta'_{ML} = \beta_{ML}/\alpha_{M(OH)}\alpha_{L(H)} \quad [13]$$

The function  $\beta'_{ML}$  versus pH for a number of EDTA complexes of metals is shown in **Figure 7**. Such plots are of direct use in optimizing conditions for compleximetric titrations. They can be further combined with  $\alpha$  coefficients for masking reagents, as shown by the dashed line in **Figure 7** for  $1 \text{ mol l}^{-1}$  ammonia buffer.

**Table 2** The  $\alpha_{M(H)}$  coefficients for metal ions in aqueous solutions for ionic strength 0.1 and temperature 20°C

**Figure 4** Dependence of side-reaction coefficients, as  $\log \alpha_{M(OH)}$ , for some metal ions (cf. **Table 2**).

The coupled effect of pH change and redox potential on the equilibrium position of analytical reactions is very important. For some reactions the pH effect is evident from the equation of the chemical reaction considered, e.g., in the case of the redox reaction in the  $MnO_4^-/Mn^{2+}$  system:

Here a pH decrease shifts the equilibrium to the formation of  $Mn^{2+}$ . Other types of reactions do not

**Figure 5** Dependence of solubility of some metal hydroxides on pH. Solubility is expressed as  $pM'$ , where  $M'$  is the total concentration of all soluble metal species in equilibrium with the insoluble hydroxide.

show direct evidence of a pH effect, e.g., the  $Fe^{3+}/Fe^{2+}$  system. However, in this system both participants are pH sensitive through their side reactions (the formation of hydroxo complexes) and undergo changes in their redox potentials. This complicated situation is usually presented in the form of a logarithmic diagram called a Pourbaix diagram. Such diagrams can be plotted for reactions that occur in

**Figure 6** Dependence of the conditional solubility product,  $K'_{s0}$ , on pH for some selected slightly soluble precipitates.

**Figure 7** pH dependence of conditional stability constants,  $\beta'_{ML}$ , of some analytically important EDTA-metal complexes. The dashed line indicates the effect of  $1 \text{ mol l}^{-1}$  ammonia/ammonium ion buffer on the conditional constants of the Zn-EDTA complex.

the absence of other reactants except those that are present in the aqueous media (Figure 8) or in the additional presence of, e.g., complexing substances.

**Figure 8** The predominance diagram (Pourbaix diagram) indicating the pH-redox potential interaction for manganese species in aqueous solution. The dotted lines indicate the thermodynamic water stability region. The full lines correspond to  $1 \text{ mol l}^{-1}$  concentration of species in the liquid phase, the dashed lines to  $10^{-2} \text{ mol l}^{-1}$  concentration.

All protolytic reactions (which include many separation and determination procedures) are influenced by pH. An example is the extraction of certain metal chelates, which is the basis for separation, preconcentration, and determination of metal ions. For the extraction reaction:

the distribution ratio,  $D$ , is related to the extraction constant,  $K_{\text{ex}}$ , the reagent concentration,  $[\text{H}_2\text{L}]$ , and the pH of the aqueous phase:

$$\log D = \log K_{\text{ex}} + n\text{pH} + n \log [\text{H}_2\text{L}]_{\text{org}} \quad [14]$$

The pH value for which 50% of metal as its chelate is extracted, i.e.,  $D = 1$ , and for  $[\text{H}_2\text{L}] = 1$ , is equal to  $(\log K_{\text{ex}})/n$ . This is termed  $\text{pH}_{1/2}$ , and has a value characteristic for the particular reagent, solvent, and the metal ion being determined. For example, in the case of metal extraction in the form of dithizonates using carbon tetrachloride as a solvent, the  $\text{pH}_{1/2}$  values for Pb(II), Zn(II), In(III), and Bi(III) are 8.0, 5.0, 3.8, and 2.0, respectively. Similar considerations apply to other chelating reagents as, e.g., 8-hydroxyquinoline, acetylacetone, and thenoyltrifluoroacetone. Such relationships are often presented in graphical form (Figure 9).

**Figure 9** The extraction percentage versus pH diagram for some metal dithizonates extracted by carbon tetrachloride.

A number of examples of the pH effect on the position of the half-wave potentials in polarography can be found when pH directly influences the  $\alpha$  coefficients of the metal ion as well as the protonation of the buffer components in particular complexing ligands, such as polyamine polycarboxylic acids. These two effects often shift the wave toward more negative potentials. However, strictly thermodynamic considerations do not always make prediction possible as kinetic factors (reversibility of the electrode process) may also contribute to the final result.

## pH in Nonaqueous and Mixed Solvents

The pH concept is most commonly used for dilute aqueous media; however, a similar formalism can be extended to other systems. The extent of the pH scale, which in aqueous media can be described as 14 units, depends on the autoprotolysis constant of the amphiprotic solvent, so that the equivalent range, e.g., in methanol, equals 16.7 units, in sulfuric acid 2.9 units, and in acetic acid 14.5 units. In such solvents, as in water, the pH of neutrality corresponds to the middle of this range. Such reasoning cannot be extended to protophilic (e.g., pyridine, ethers), and aprotic (e.g., hydrocarbons) solvents, for which the  $\log a_{H^+}$  scale is from one or both sides, respectively, unlimited.

The mutual correlation of pH scales in different solvents creates more problems as a number of effects must be considered, such as electric permittivity and the solvation of ions. Potentiometric measurements of the hydrogen ion activity can be made using the hydrogen electrode in many solvents; however, more difficulties are concerned with the reference electrode. When using an aqueous reference electrode the liquid junction potential on the boundary of two solvents is large. For a reference electrode in a nonaqueous solvent the interactions of various ions must be considered. Some good approximation can be reached when the reference electrode uses a

system that is not influenced by solvation processes. At least, in principle, such a system may be based on the redox couple ferrocene/ferricinium ion. The potential of the cell

should, at least, in principle, be independent of the solvent, and give the measure of the actual proton activity in those solvents. The activity of the proton in one solvent can be correlated to that in another solvent. Denoting the activity of the solvated proton  $(a_{H^+})_S$  in the solvent S, and  $(a_{H^+})_W$  in water, then

$$(a_{H^+})_W = (a_{H^+})_S \gamma_{t(H^+)} \quad [15]$$

where  $\gamma_{t(H^+)}$  is the activity coefficient for transfer of the  $H^+$  ion from solvent S into water (at infinite dilution). On such a basis it is possible to correlate the pH scales for different solvents. Similar considerations can be applied to mixed organic–aqueous systems.

In each individual solvent system the practical use of pH is based on standard buffer solutions, which have been proposed, e.g., for water–methanol and water–ethanol systems.

## Experimental Determination of pH

The oldest method of pH determination is based on the color change of some natural or synthetic dyes, either in the form of a solution or as indicator papers. Even in the best case the accuracy of pH determination is not better than 1 pH unit. Somewhat more accurate (uncertainty 0.1 pH) may be achieved by the spectrophotometric measurement of absorbance of a solution containing such indicators. The pH range for a single protonation equilibrium of the indicator spans not more than 2 pH units around the pH value corresponding to the  $pK_H$  value of the indicator. The disadvantage of optical pH sensing is the effect of other colored substances present in the sample and the influence of macromolecular species such as proteins. The change of the color of the indicator is also the basis of optodes sensitive to pH. The indicator is immobilized in a polymeric film at the sensor end that is in contact with the sample. The dissociation characteristic of the indicator in those conditions may be significantly different from that known for dilute aqueous media. Besides, the optode senses the pH value at the solution–sensor interface, which may differ from that in the bulk sample solution. On the other hand, absorbance measurements do not need a reference sensor, contrary to the electrochemical measurements.

The most common electrochemical procedures of pH evaluation are based on potentiometric measurements. The theoretically best described is the hydrogen electrode, consisting of platinum metal in contact with hydrogen gas but its use, however, is restricted to specialized laboratories. The various types of glass electrodes offer a wide pH range of dynamic response, which only at the ends of the pH scale may be subject to acid or alkaline errors. The glass electrodes are of various constructions, both macro and micro down to the micrometer scale. Most convenient for routine measurements are glass electrodes mounted in one body with the reference electrode. The uncertainty of electrochemical pH measurements is usually below 0.02 pH unit but may depend on the construction details of the cell. For special applications the glass electrode can be replaced by some metal/metal oxide electrodes, of which the antimony electrode is most commonly used. However, such sensing electrodes are more sensitive to the presence of redox species in the sample solution. Sensors that recently became more popular are those with polymeric membranes, containing a pH sensitive carrier such as tridodecylamine. Their use in nonaqueous media is often restricted, and their lifetime is often shorter than that of glass electrodes.

## Introduction

Pharmaceutical analysis is traditionally defined as analytical chemistry dealing with drugs both as bulk

drug substances and as pharmaceutical products (formulations). However, in academia, as well as in the pharmaceutical industry, other branches of analytical chemistry are also involved, viz. bioanalytical chemistry, drug metabolism studies, and analytical biotechnology. The development of drugs in the pharmaceutical industry is a long-term process, often taking more than a decade from the start of the research project to appearance of a drug on the market. That process involves several decision points, such as the choice of the candidate drug after the discovery phase, the application to the authorities before

## Introduction

An exhaustive overview on pesticides should include aspects referring to their synthesis and formulation (and related quality control features), mechanisms of action, degradation and/or metabolism patterns, and their impact on environment and living organisms, including on human health. Analytical chemistry is directly involved in all these domains and takes into account at least three major difficulties: extreme diversity of the target compounds, increased sample matrix complexity, and imposed levels of detectability, which are continuously decreasing. The article starts by defining pesticides and related topics together with their classification criteria and class exemplification. Thus, attention is focused on the

analytical contributions to the topic. The sample preparation approach reviews analytical techniques involved in the isolation, concentration, and derivatization of pesticides and pesticide residues from real samples of different origin (environmental, food, clinical, forensic, etc.). Recent developments such as focused microwaves Soxhlet extraction, solid-phase extraction and microextraction on immunosorbents, shielded materials and molecular imprints, stir-bar sorptive extraction, supported liquid membrane extraction, and supercritical fluid and pressurized fluid extractions are discussed. The main achievements related to pesticide separation by means of thin layer, gas, liquid, supercritical fluid, micellar electrokinetic, and capillary electro-driven chromatographic methods are also discussed. Special emphasis is given to mass spectrometric detection for its inherent selectivity and high sensitivity. In some circumstances, other analytical methods such as spectrometric, immunochemical, and electrometric (including bio- and immunosensors) methods can be successfully used for pesticide analysis. Due to the complexity of the subject, more often only recent advances have been detailed at some length.

## Classification

Pesticides are classified according to the following criteria:

1. the target pest they are intended to destroy (see Table 1);
2. their mode of action (see Table 2);
3. their nature (see Table 3);
4. type of formulation in which a pesticide is included (see Table 4); and
5. their impact on health (see Table 5).

In order to illustrate the large variety of compounds used as pesticides, the main chemical classes belonging to fungicides and insecticides are listed in Table 6.

## Sample Preparation

As shown in Figure 3, sample preparation methods applied to pesticide analysis are widely different. The

sophistication of the procedure varies depending on the type of sample to be analysed, its size, and corresponding concentration levels of the target compounds. More often, two or three successive sample preparation techniques need to be applied to a sample in order to achieve analyte concentration and to eliminate the matrix interferences efficiently.

For practical reasons, classical procedures are continuously upgraded to get improvements in terms of reliability and performance. Such an approach relates, for example, to the conventional Soxhlet extraction assisted by focused microwaves (FMSE). The main factors affecting extraction efficiency are microwave power, irradiation time, volume of the extractant, and number of cycles. The result, in terms of extracted mass and repeatability is similar to the classical method. In addition, there is a significant reduction in the total time taken for the process and far less amount of extractant is consumed. Organochlorine pesticides (OCPs) and related residues have been successfully isolated from sunflower seeds by means of FMSE. Comparison with the ISO 659-1988

**Table 1** Classification of pesticides according to the target pest they are intended to destroy

No.	Pesticide class	Synonyms	Target
1	Acaricides	Miticides	Mites feeding on plants and/or animals
2	Algicides	—	Algae from aquatic media (lakes, canals, swimming pools, water tanks)
3	Antifouling agents	—	Living organisms, attaching to underwater exposed surfaces (e.g., boat bottoms)
4	Avicides	—	Birds
5	Biocides	Bactericides	Microorganisms
6	Fungicides	—	Fungi (including blights, mildews, and rusts)
7	Herbicides	—	Weeds
8	Insecticides	—	Insects or other arthropods
9	Molluscicides	—	Snails and slugs
10	Nematicides	—	Nematodes (microscopic worm-like organisms feeding on plant roots)
11	Ovicides	—	Eggs of insects and mites
12	Rodenticides	—	Mice and other rodents
13	Virucides	—	Viruses

**Table 2** Classification of pesticides according to the mode of action

No.	Pesticide class	Function
1	Antifeedant	Inhibits feeding due to inherent toxicity or taste
2	Attractant	Attracts pests to a trap
3	Chemosterilant	Generates sterility of an organism on ingestion
4	Defoliant	Determines dropping of leaves or other foliage from plants
5	Desiccant	Promotes drying of living tissues
6	Fumigant	Releases gas or vapors intended to destroy pests
7	Growth regulator	Alters the expected growth, flowering, or reproduction rate of plants; Disrupts molting, maturity from pupal stage to adult or other life processes of insects
8	Mating disrupter	Acts on mating behavior of insects (e.g., pheromones)
9	Plant incorporated protectant (PIP)	Exogenically induced genetic material determining self-production of substances destroying pests
10	Repellent	Repels pests (avian, insect, mammal)
11	Safener	Increases tolerance of crops to the toxic effects of herbicidal compounds
12	Synergist	Amplifies the specific action of a pesticide

**Table 3** Classification of pesticides according to their nature

No.	Pesticide class	Characterization
1	Inorganics	Synthetic or naturally occurring inorganic compounds exhibiting pesticidal action
2	Organics	Synthetic organic compounds exhibiting pesticidal action
3	Biochemicals	Naturally occurring substances controlling pests by means of nontoxic mechanisms
4	Microbials	Microorganisms (bacteria, fungi, viruses, protozoans, nematodes) affecting pest metabolism

**Table 4** Classification of pesticides according to the type of formulation

No.	Pesticide class	Type of formulation
1	Granulars	Inert carrier impregnated with the active agent or active mixture
2	Dusts	Undiluted active agents representing solid materials with low granulometry
3	Baits	Target-oriented active agents (generally acting after ingestion) with practical no impact on environment
4	Coatings	Active agent deposition in a film covering a surface (e.g., leaves, seeds)
5	Aerosols	Air-suspended solid microparticles or droplets of active agents as such or in solution
6	Slow release formulations	Microencapsulated active agents, paint-in lacquers or resin strips for indoor use

**Table 5** Classification of pesticides according to their impact on health*Classification of pesticides by hazard**(according to the World Health Organization – WHO)*

No.	Class	Hazard	LD <sub>50</sub> (mg per kg) in rats			
			Oral		Dermal	
			Solids	Liquids	Solids	Liquids
1	Ia	Extreme	≤5	≤20	≤10	≤40
2	Ib	High	5–50	20–200	10–100	40–400
3	II	Moderate	50–500	200–2000	100–1000	400–4000
4	III	Slight	> 500	> 2000	> 1000	> 4000

*Classification of pesticides according to their carcinogenic risk on humans**(according to the International Agency for Research on Cancer – IARC)*

No.	Class	Carcinogenicity	Evidence on humans	Evidence on animals	Other supporting evidence
5	1	Carcinogenic	Sufficient Insufficient	Sufficient	Mechanism of carcinogenicity possible in humans
6	2a	Probably carcinogenic	Limited Inadequate	Sufficient Sufficient	Mechanism of carcinogenicity possible in humans
7	2b	Possibly carcinogenic	Limited Inadequate Inadequate	Less than sufficient Sufficient Limited	Other evidence
8	3	Not classified as carcinogenic	Inadequate Inadequate Inadequate	Inadequate Limited Sufficient	Mechanism of carcinogenicity not possible in humans
9	4	Probably not carcinogenic	Evidence of the lack of carcinogenicity Inadequate	Evidence of the lack of carcinogenicity Evidence of the lack of carcinogenicity	Other evidence

reference extraction method confirmed that FMSE is a more efficient process.

In the field of solid-phase extraction (SPE) methods, research is oriented toward the identification and synthesis of new sorbents with increased selectivity. It has already been shown that polar adsorbents such as Oasis HLB (vinylpyrrolidone-divinylbenzene copolymer) can isolate organophosphorous pesticides from blood or serum, or triazines, acetamides and phenoxy acids from surface and waste water. Recently, a new polymeric material, polyaniline, was introduced for the extraction of chlorophenolic pesticides in water samples. Immunosorbents produced by covalent immobilization of the antibody generated against the target analyte on

inert materials (silica gel or activated agarose gel) were successfully used for the isolation of analytes from complex matrices. Thifluzamide in peanut samples and imazalil in citrus fruits have been rapidly isolated using immunosorbents. Target-tailored materials have also been developed by molecular imprinting technologies. 2,4,5-Trichlorophenoxy acetic acid has been used as a template in a system of 4-vinylpyridine as monomer, ethylenedimethacrylate as reticulation agent, and methanol/water mixture as porogen. A molecularly imprinted polymer for the isolation of pirimicarb is based on methacrylic acid as functional monomer and ethyleneglycoldimethacrylate as cross-linker. Some other materials have especially been developed for specific

**Figure 3** General analytical process for pesticide-containing samples.

matrix elimination. Restricted access or shielded materials selectively eliminate macromolecular compounds from pesticide-containing samples (e.g. soil extracts, serum, plasma). Basically, the hydrophilic character of the external particle's surface and the lipophilic character of the inner pore surfaces in these materials are responsible for their intrinsic capabilities of discrimination, combining size exclusion and polarity based interaction mechanisms.

The quest for new suitable materials represents a similar trend in the development of the solid-phase microextraction (SPME) techniques. Polypyrrole and poly *N*-phenylpyrrole films exhibit better selectivity toward polar, aromatic, and basic pesticides, due to their inherent multifunctional properties. Their high surface areas (also revealed by scanning electron microscopy) are responsible for the high extraction efficiencies shown by these materials. Mixtures of divinylbenzene, carboxen, and polydimethylsiloxane-based

fibers have been used for the isolation of cyprodinil and fludioxonil in white wines, while carbowax-templated resins exhibit selectivity towards chlorophenols in environmental samples.

The stir bar sorptive extraction (SBSE) technique, which serves as a more robust alternative to SPME, has been applied for the determination of dicarboximide fungicides in wines.

Microporous membrane liquid-liquid extraction of lipophilic pesticides in biological fluids combines the size exclusion properties of the membrane, reducing lipid coextraction, with the stirring capabilities of the sample phase together with the permanent pumping of the organic phase.

Hollow fiber membranes are used for preconcentration of nitrophenolic pesticides in water samples. The mechanism is based upon the pH difference inside and outside the hollow fiber, while the organic solvent is immobilized within the pores of the

membrane. Such liquid–liquid–liquid microextraction device is suitable for interfacing with micro-column liquid chromatography.

Supported liquid membrane extraction (SLME) is emerging as a fast and efficient sample preparation technique. Aromatic aminophosphonate isolation from water samples based on SLME allowed the identification and study of the operational parameters (pH and ionic strength of the aqueous phase, composition of the membrane phase, and concentration of analytes) as well as the structure–extraction efficiency relationship.

Given the increasing complexity of samples, it becomes imperative that the preparation techniques are highly reliable. This necessitates minimal effort and duration combined with enhanced accuracy and precision. Supercritical fluid extraction (SFE), pressurized fluid extraction (PFE), and assisted solvent extraction (ASE) procedures have been developed as reliable alternatives to traditional methods of sample preparation.

Combining the properties of supercritical fluids and/or extraction solvents with pressure/temperature/density effects and automatically controlled static/dynamic setup results in an increased flexibility and efficiency of the previously cited methods. However, two practices related to SFE/PFE/ASE processes should be mentioned. The first relates to fixation effects in the extraction thimble. Such practice was discovered during development of SFE procedures for pesticide determination in fruit juices (diatomaceous earth was ‘solidifying’ liquid samples). Addition of silica onto solid vegetal materials (such as tobacco leaves) proved to induce a major matrix removal effect during analysis of OCPs. All pesticides enlisted in the 608 EPA method were 100% recovered by means of such a practice at a concentration level of  $10 \text{ pg l}^{-1}$ . The other practice relates to *in situ* derivatization of target analytes during SFE/PFE/ASE procedures. Pesticides containing carboxyl or phenol groups were readily derivatized simultaneously using PFE by using acetic anhydride for acetylation, *N,O*-bis(trimethylsilyl)trifluoroacetamide (BSTFA) for silylation and borontrifluoride/methanol, phenyltrimethylammonium hydroxide, and trimethylsulfonium hydroxide for methylation. Subcritical extraction conditions are sometimes preferred (especially when using water as the extraction agent for pesticides from soil samples). Under optimized conditions, most of the analytes are quantitatively extracted within 90 min. *In situ* degradation of the target compounds in order to generate class markers has also been practised for nonpersistent pesticide analysis in biological samples. 3,4-Dichloroaniline and 3,5-dichloroaniline

as markers for the exposure to fungicides such as vinclozolin, procymidone, iprodione, chlozolate and herbicides such as diuron, linuron, neburon, and propanil, respectively, are generated by the *in situ* hydrolysis simultaneously carried out with steam distillation (SD) removal, followed by liquid–liquid extraction, derivatization with heptafluorobutyric anhydride, and gas chromatography/electron-capture detection.

Last but not least, nanofiltration, a technique derived from technologies used for removing hazardous organic micropollutants, should be considered as a promising tool for sample preparation methods.

Some examples of sample preparation procedures used for pesticide isolation and concentration are given in Table 7.

## Gas Chromatography

Gas chromatography should be considered as the principal primary screening method for pesticide analysis in food, environmental, and clinical samples.

Due to the broad range of polarity characterizing the analytes, separations are achieved on stationary phases that possess different polar characters. Consequently, the open tubular columns with silicone polymer bonded phases that are used range from 100% methyl silicone or 95% methyl and 5% phenyl (apolar) to 50% methyl and 50% phenyl, 50% methyl and 50% trifluoromethylpropyl, 86% methyl and 14% phenylcyanopropyl, or 50% methyl and 50% phenylcyanopropyl (medium polar or highly polar). The primary choice with respect to the stationary phase for screening residues of pesticides is a low polarity one, either 100% methyl silicone or 95% methyl and 5% phenyl.

Considering the close relationship between the deactivation degree of the column wall and the deposited layer of the stationary phase, use of films thinner than  $0.1 \text{ }\mu\text{m}$  should be avoided, especially for the separation of labile pesticides. Fused silica open tubular columns of 25–30 m length, 0.20–0.25 mm internal diameter, and 0.15–0.33  $\mu\text{m}$  film thickness should be considered as the first choice.

Low-pressure gas chromatography (LPGC) is also used for the fast analysis of multiple pesticide residues, mainly for food applications. The LPGC/mass spectrometric detection (MSD) technique uses an analytical 0.53 mm internal diameter column and 1  $\mu\text{m}$  thick film coupled to a 0.15 mm inner diameter restriction capillary at the inlet side. While the injection conditions are similar to conventional GC methods, subatmospheric pressures occur through the column because of the MS vacuum source.

Optimized conditions allow faster separations (three-fold reduction), substantial increased injection volume capacity, reduced degradation of thermally labile compounds, and lower detection limits due to increased sample loadability.

Nitrogen, helium, and hydrogen are the carrier gases commonly used in GC. Hydrogen is not suitable for some selective GC detectors, while nitrogen exhibits less flat Van Deemter curves for gas velocities higher than optimal. Thus, helium remains the best choice.

As injectors for capillary GC separation of pesticides and related residues, cold on-column (OCI), hot splitless injector (HSI), and programmed temperature vaporizer (PTV) are mainly used. Injection of thermally unstable analytes can be controlled via pressure pulses (based on electronic pressure controlled systems – or EPC systems), by precise temperature control during injection (achieved by PTV), and by the presence of suitable chemical additives. As an example, phenylureas in conventional hot splitless injectors lead to extensive and irreproducible formation of isocyanates and amines. The presence of acetic acid, low molecular mass amines, and organic anhydrides during injection result in minimization of the thermal decomposition effect or reproducible conversion to the corresponding isocyanates. Studies carried out on organophosphorous and carbamate pesticides, in parallel, on PTV splitless, PTV solvent split, pulsed splitless, and on-column injectors lead to the following hierarchical tolerance: OCI < pulsed HSI < PTV splitless < PTV solvent split. Some other phenomena are associated with injection systems. Tralomethrin, for example, is quantitatively transformed to deltamethrin in HSIs. The latter, when vaporized in packed liner-fitted PTVs, readily isomerizes, leading to splitting of the chromatographic peak into two equally intense peaks that are baseline separated, corresponding to the *cis* and *trans* isomers. Derivatization may also enhance thermal stability. Phenylurea pesticides are alkylated with iodoethane and sodium hydride to yield thermostable compounds. When using MSD and iodoethane instead of iodomethane, differentiation between the parent compounds and *N*-demethylated metabolites is possible.

The use of a retention gap between the injection port and the capillary column has been widely discussed in the literature, especially for OCI. The influences of the solvent, the gap geometry, the injection volume, and the analyte concentration on peak efficiency and symmetry do not lead to a general accepted recommendation considering the use of retention gaps. Checking for each particular case is more advisable.

Peak tailing processes due to undesired interactions of the analytes with the active sites in the inlet and the chromatographic column occur with a relative high incidence in GC analysis of pesticides. For susceptible analytes, significant peakshape improvements are obtained when matrix components are present because of their specific competitive interactions with the active sites (the so-called matrix-induced chromatographic response enhancement). Some of the reported applications deal with ‘analyte protectants’ for providing a convenient and effective solution for the enhancement of chromatographic response. Most of such compounds spiked to real samples have hydrogen bonding capabilities in order to preferentially interact with the active sites (sugar, sugar derivatives, and gulonolactones are used).

Detection systems used for GC analysis of pesticides belong to the following categories: (1) classical selective and sensitive detectors such as electron-capture detector (ECD – including the pulse modulated setup and the microdesign); nitrogen–phosphorous detector (NPD – including the separate electrical heating of the alkali bed design); flame photometric detector (FPD, including the sealed chimney, the double burner, and the pulsed flame designs); and (2) structural information detectors, mainly the MSD and the atomic emission detector using the microwave-induced plasma (AED-MIP).

Both electron impact (EI) and chemical ionization (CI) are currently used as ionization techniques in MSD, in addition to the positive or negative ion monitoring modes. The use of the selective ion monitoring (SIM) feature improves the sensitivity greatly, although some structural confirmation is lost. In Table 8, the ion fragments frequently monitored in MSD for some pesticides separated by GC are listed.

AED provides molecular confirmation by means of its ability to calculate the molecular formula by means of the responses obtained on the simultaneously monitored specific element channels. It is worth noting that sensitivity is tuned according to the chemical element monitored (e.g., acephate is characterized by a 5 ng detection limit when monitoring the nitrogen channel, 3 ng for phosphorous, 10 ng for oxygen, and 0.3 ng for sulfur).

## Liquid Chromatography

The main reasons for the failure of GC methods in pesticide analysis are thermal lability, low volatility, and high polarity of some target analytes. There are a relatively reduced number of classes of pesticides that are not suitable for GC separation

**Table 8** Major *m/e* signals in the mass spectra of some pesticides separated in gas chromatography with mass spectrometric detection (ionization by electron impact)

No.	Pesticide	Class	Chemical classification	Major <i>m/e</i> signals in the mass spectrum

D, defoliant.

and which therefore require the use of liquid chromatography (LC). Phenylurea, carbamates, dinitrophenols, benzimidazoles, azoles, benzoylureas, some organophosphorous, pyrethroid, and quaternary ammonium derivatives are some examples for such pesticides.

In LC, the separation mechanism favored for the separation of pesticides is undoubtedly the reversed phase (RP) chromatography. However, ion exchange (IE) and ion pair (IP) mechanisms are also used, especially for quaternary ammonium derivatives (quats). In RP applications, polar end-capped octadecyl silica gel stationary phases are especially recommended for separations requiring high content or even 100% aqueous mobile phases (e.g. separation of water unextractable organophosphorous pesticides such as acephate, methamidophos, monocrotophos, omethoate, oxydemeton-methyl, and vamidothion). More often, the addition to mobile phases of concentrated buffers or strong acids is needed in order to stabilize the analytes in a single form. When tautomeric equilibrium is competitive to chromatographic partition, the peakshape and symmetry are strongly affected. Sometimes, the inherent selectivity of LC affords separation of the tautomeric structures, leading to serious peak splitting, mainly

at low concentration of the target compounds. **Figure 4** gives an example showing tautomerism of chlorophacinon and diphacinon rodenticides, whose stabilization requires addition of strong acid to the mobile phase. Normal phase (NP) mechanism is used only for achieving enantioselective separations. Enantiomers of the organophosphorous pesticides crotoxyphos, dialifor, fonofos, fenamiphos, fensulfothion, isofenphos, malathion, methamidophos, profenophos, crufomate, prothiophos, and trichloronate have been separated successfully on polysaccharide-based chiral stationary phases (ChiralPak AD, AS, OD and OJ) under NP conditions.

Micro-LC columns are used for better compatibility with specific sample preparation methods (e.g. on-column focusing) or interfaces for MSD. The use of microcolumns also enables temperature gradient as an additional selectivity/efficiency tuning factor. Applications on triazines use temperature gradients ranging from subambient conditions up to 70°C.

It is worth noting that robust online configurations between SPE or SPME sample preparation techniques and LC separations have been reported, which have lead even to commercially available dedicated devices (e.g. SAMOS, OSP2A).

**Figure 4** Chlorophacinone and diphenadione's tautomerism in aqueous media.

For pesticide separations by LC, different calibration approaches were studied. Among 'external solvent solubilized standard', 'internal standard', 'external matrix-matched standard', and 'echo peak internal standard' approaches, the last two procedures generate better results. The 'echo peak internal standard' is a novel technique based on the possibility of producing a delayed injection of an internal standard having the same identity as the target compound.

Detection systems used for LC analysis of pesticides are: UV spectrometric detection (especially diode array detection – DAD – allowing peak confirmation by means of spectra comparison), fluorescence detection (FLD), electrochemical detection (ED), evaporative light scattering detection (ELSD), and MSD. Their characteristic sensitivities can be considered to vary in the following order: ELSD < UV (DAD) < ED ~ FLD < MSD. Particle condensation nucleation practices are also expected to enhance ELSD sensitivity. Among the detection systems mentioned above, only ELS and MS are universal detectors.

UV or FL detection of the target compounds is sometimes not achievable due to the lack of suitable chromophoric/fluorophoric molecular sites. This could be overcome by derivatization. Two postcolumn derivatization modes are noticeable for pesticide detection. One relates to the fluorescent detection of carbamates based on their reaction with *ortho*-phthalaldehyde (OPA), and the other deals with the photoirradiation of benzoylurea insecticides (namely diflubenzuron, triflumuron, hexaflumuron, lufenuron,

and flufenoxuron) or pyrethroids (namely phenpropathrin, cyfluthrin, deltamethrin, fenvalerate, acrinathrin,  $\tau$ -fluvalinate, and bifenthrin) with production of highly fluorescent photodegradation products.

Detection according to (geno)toxicity has been reported recently. Such system is based on the collection over microtiter plates of 1 min eluate fractions. After evaporation and redissolution in suitable solvents, the (geno)toxicity of each individual fraction is determined before and after enzyme activation, by means of the umu test. (Geno)toxicity is measured against 4-nitroquinoline-*N*-oxide and 2-aminoanthracene standards, exhibiting detection limits of the order of  $0.1 \mu\text{g l}^{-1}$ .

MS is undoubtedly the solution of the near future for LC detection. Improvements made to interfacing devices together with a continuous and sensible diminution of instrumentation costs promote MS as a universal/selective tunable detection system. Atmospheric pressure electrospray ionization (ESI) and atmospheric pressure chemical ionization (APCI) are the most robust and popular devices for interfacing MS to LC systems. In Table 9, LC–MS data for some pesticides are given. Although ESI and APCI are more often used, other LC–MS interfaces produce reliable results in pesticide applications: thermospray (TSI), particle beam (PBI) and matrix-assisted post-source decay laser desorption/ionization (CID-PSD-MALDI).

Multidimensional techniques (MS/MS or (MS)<sup>n</sup>) enable finding the right ratio between selectivity and sensitivity of the detection process.

## Supercritical Fluid Chromatography

Packed column supercritical fluid chromatography (P-SFC) offers an interesting alternative for pesticide separations based on the normal phase partition mechanism, even when using apolar modified stationary phases. Reproducible retention, high selectivity, and good peak symmetry are obtained on applying both density/pressure and modifier gradients. Online coupling of SFC with SPE or SPME (desorption is made by the supercritical mobile phase) results in high extraction yields and sample throughput. Interfacing with MSD (both ESI and APCI) does not require any modification of the commercialized interface designs but only an additional solvent flow, generally introduced before the automated pressure relief valve (nozzle) of a downstream configuration. A similar setup based on the introduction of an additional suitable solvent flow through the nozzle leads to a versatile SFC semi-preparative or even preparative fraction collection/isolation alternative, allowing fast (automated) off-line bidimensional separation techniques. Extremely selective, reproducible, and fast SFC applications relate to chiral separation of pesticide racemics on chemically modified polysaccharides or to antibiotic modified stationary phases.

## Thin-Layer Chromatography

Thin-layer chromatography (TLC) is more often associated with the screening of pesticides, especially from water samples. The automated multiple development (AMD) feature significantly increases the separation capacity and the versatility of the method. The AMD approach uses more than 25 different development steps (1–3 mm migration distance each) with intermediate drying steps, the mobile phase composition or nature changing continuously from step to step. Both mobile phase change and drying are done in an automated way, AMD-TLC equipments are now commercially available. In fact, the entire procedure represents the application of three or even more different step composition gradients during a single run over TLC silica plates having thickness higher than 100  $\mu\text{m}$ . Because of intermediary drying steps, each new development generates focusing of the spots, finally leading to extremely sharp lines. Sample throughput of the method should be considered as satisfactory since 12–24 sample applications are feasible on a single TLC plate. By associating densitometry detection, quantitative determinations are possible, and currently research efforts are underway to produce UV-Vis reflectance spectra of the separated spots. Structural confirmation

and sensitive quantitation are made possible by scratching spots from plates followed by analyte extraction from the solid material in appropriate solvents and subsequent introduction in a mass spectrometer. Standardization of AMD-TLC as a DIN method for pesticide determination in ground and drinking water dates back to 1993.

## Micellar Electrokinetic Chromatography and Capillary Electrochromatography

Micellar electrokinetic chromatography (MEKC) and capillary electrochromatography (CEC) are powerful techniques for achieving efficient pesticide and pesticide residue separations, although accepted standardized methods are still missing. The *N*-methylcarbamates, carbendazin, imazalil, methylthiophanate, prochloraz, procimidon, thiabendazole, triadimefon, metribuzin, lenacil, ethofumesate, atrazine, terbuthrin, isoproturon, chlorotoluron, linuron, desethyl atrazine, 2-hydroxyatrazine, desethyl 2-hydroxyatrazine, and 3-chloro-4-methylphenyl urea are only some of the pesticides that have been reported to be separated by means of MEKC and CEC. Online coupling of MEKC with ESI-MS was recently found as achievable using partial filling (PF) or reverse migrating micelles (RMM) techniques. Quantitative migration-toxicity relationship for phenoxy acid herbicides has been obtained with MEKC on using micellar Brij 35 based migration media. Online stacking procedure carried out on injection acts as a preconcentration step and together with SPE for sample preparation shifts the detection limits to the low  $\mu\text{g l}^{-1}$  range, even on use of the classical on-column diode array detection.

## Capillary Electrophoresis

Capillary electrophoresis (CE) represents an important tool with several advantages for determining pesticides and pesticide residues in environmental samples due to its intrinsic simplicity and high efficiency. Target analytes should be ionic or easily ionized. Some limitations arise from a lack of selective detectors, although CE-MS interfacing has become more affordable.

## Immunochemical Assays

Immunoassays (IAs) are based upon the selective interaction between a specific antibody (Ab) and a hapten (H or antigen – Ag). Pesticides are not ordinarily antigenic; consequently they have to be

**Table 10** Immunochemical assays for some pesticides

No.	Pesticide	Class	Chemical class	Test format	Ag Type	Detection limit ( $\mu\text{g l}^{-1}$ )	Sample type

conjugated to a carrier molecule (usually a protein) in order to induce an immune response. The result of the binding reaction between the Ab and H can be measured by means of enzymatic methods (EIAs), radiometric methods (RIAs), fluorescence methods (FIAs, including the polarized PFIA approach), or chemiluminescence methods (CLIAs). Some of the immunoassays designed for pesticides are given in Table 10, together with the corresponding detection limits.

## Spectrometric Methods

Spectrometric methods are more often used for pesticide analysis in formulations. However, some spectrometry-based screening methods for environmental and biological samples have also been reported. Powerful structural elucidation spectrometric techniques (such as nuclear magnetic resonance spectrometry – NMR) have been also extensively used for the investigation of degradation

patterns of parent pesticides, mainly in biological systems. Derivatization is often needed for introduction of chromophores, fluorophores, or luminophores in the target molecules. A few recent examples of pesticide analysis by means of spectrometric methods are given in Table 11.

## Bio- and Immunosensors

Bio- and immunosensors are systems based on measurement of the results generated by means of binding to a specific receptor of the target analyte. The basic construction of a biosensor for pesticide analysis is schematically given in Figure 5. The main advantages related to bio- and immunosensors is because of the high sample throughput, any or limited sample preparation procedures, *in situ* measurement capabilities, and selectivity. The main drawbacks are related to inherent matrix interferences (mainly on biosensors), limited shelf-life, difficulties for coupling

**Table 11** Spectrometric techniques used in pesticide analysis – few recent applications

No.	Pesticide (class or compound)	Spectrometric technique	Sample	Details on experiments
1	Isothiocyanates and dithiocarbamates	UV	Biological fluids	Cyclocondensation with benzenedithiol
2	Carbaryl	UV	Formulations	Coupling/complexing with 2-amino-4-nitrophenol and 2,4-dimethoxy aniline; detection in the 510–520 nm interval
3	Carbofuran	UV	Formulations	Hydrolysis followed by derivatization with sodium nitroprusside; detection 530 nm
4	Organochlorinated	Tunable dye laser absorption spectrometry	Water	Detection limits $\sim 10^{-3}$ – $10^{-4}$ $\mu\text{g g}^{-1}$
5	Organochlorinated	Laser induced fluorescence (LIF)	Water	Detection limits $\sim 10^{-1}$ – $10^{-2}$ $\mu\text{g g}^{-1}$
6	Carbaryl	LIF	Water	Detection limit at femtogram level
7	Benzoylurea and fenfenoxuron, lufenuron, hexaflumuron, triflumuron	Induced fluorescence (IF)	River water and formulations	UV irradiation to produce highly fluorescent degradation products
8	Morestan	Solid phase phosphorescence	Natural, tap, sea, river, waste water	Excitation 363 nm; emission 520 nm
9	Dichlorvos	Chemiluminescence (CL)	Vegetables	Chemiluminescent system with luminal, perhydrole, and cyltrimethylammonium bromide
10	Folpet and metalaxyl	FTIR	Formulations	Extraction in chloroform; detection limits $\sim 15$ $\mu\text{g g}^{-1}$
11	Chlorinated aromatic amines	IR	Water	Extraction on hydrophobic polyacrylonitrile-co-butadiene material
12	Ziram	IR (vapor phase)	Formulations	Evolution of $\text{CS}_2$ as degradation product
13	Cyromazine	Surface enhanced Raman scattering spectrometry (SERS)	Formulations	Study on surface adsorption mechanisms

receptors to supports, identification of sensitive transducers, and a relative delay in generating the response.

The measuring principle of a biosensor designed for pesticide determination is mainly enzyme inhibition. Cyanobacteria, thylakoid membranes, protoplasts, immobilized enzymes, and labeled enzymes are receptor components. The analyte blocks the enzyme, enzyme systems, or electron transport systems of intact cells.

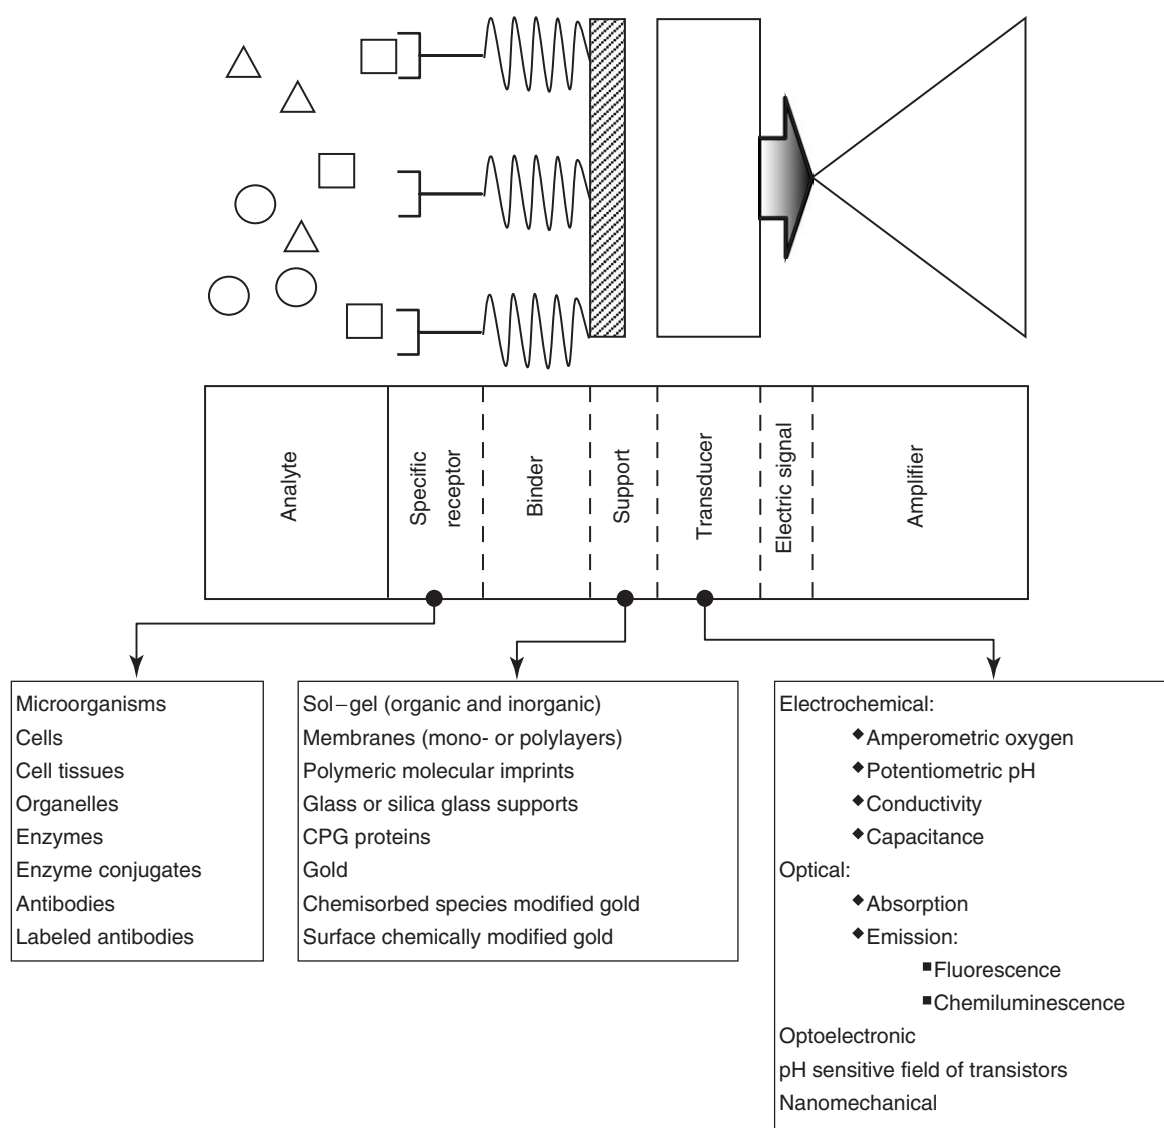

In an immunosensor, the antigen–antibody selective interaction is monitored. In order to improve the sensitivity, the indirect monitoring of the Ag–Ab interaction should be preferred, using competitive tracers or markers. Determination of alachlor, for example, can be achieved with increased sensitivity by using liposome encapsulated markers in a competitive binding reaction instead of enzymes.

The conjugation of a lipid to a pesticide allows its incorporation into a liposome structure, leading to competitive liposome IA-based sensor. The use of piezoelectric crystals as physical sensors is a continuously developing research direction. Other physical sensors are optical, such as surface plasmon resonance (SPR), interferometric, or grating couplers.

Bio- and immuno-sensors are complementary to high-resolution techniques and represent a stimulating border research area between chemical analysis and microelectronics.

## Electroanalytical Techniques

Electroanalytical techniques are often used for the determination of a target pesticide in a given matrix.

**Figure 5** Basic construction of a biosensor designed for pesticide analysis.

In order to obtain the required sensitivity levels, preconcentration techniques are needed. Adsorptive stripping voltammetry (ASV) is, in this respect, a method of choice. Specific accumulation potentials applied for 30–60 s before the measurement have shifted the detection levels to the  $10^{-7}$ – $10^{-9}$  mol l<sup>-1</sup> interval (e.g. buprofezin requires an accumulation potential of  $-0.8$  V over a period of 60 s on the hanging mercury electrode before quantitation by means cyclic voltammetry or differential pulse voltammetry, desmetryn needs an accumulation potential of  $-0.7$  V over a period of 50 s before differential pulse voltammetry determination from micellar or emulsified media). Attempts for simultaneous determination of complex mixtures of

pesticides in the same sample can generate serious overlapping of the polarographic signals. In such cases (e.g., captan, captafol, and folpet together, in river water samples), different chemometric methods such as artificial neuronal networks (ANNs) have been successfully used.

## Indirect Tests

Sometimes it is beneficial to avoid determination of the target compounds in complex samples requiring tedious sample preparation steps, as their presence, once confirmed, leads to the qualitative rejection of a product or an alert reaction. For example, existence

of quaternary ammonium pesticides in baby fruit pastes is reflected by the determination of the corresponding saccharide profile (the presence of maltose confirms adulteration of the products with sugars of cereal origin, related to potential presence of 'quats' at trace levels, and subsequently conducted to batch rejection). Ethephon (used as growth regulator and ripening accelerator in fruit and vegetable growing) is thermally hydrolyzed to ethylene, whose presence is determined by headspace GC.

## Quality Assurance in Pesticide Analysis

Analysis of pesticides in environmental, food, clinical, and forensic samples is undoubtedly a complex task because of the matrix complexity and low concentration values of the target compounds.

In order to produce accurate results, sampling, sample preparation methods, analytical methods, analytical equipments, data processing should be validated and the working personnel should be qualified. Sampling and sample storage should be, at the least, studied for representativeness and stability. In this direction, a knowledge of the sample history is essential. Sample preparation techniques should be checked for selectivity, precision, and recovery. Separation techniques and detection should be validated for selectivity, precision (repeatability and intermediate reproducibility), linearity (statistical determination of quantitation and detection limits – LOQ and LOD – included), accuracy, and robustness. Analytical instrumentation should be attentively and periodically tested (analytical column(s) should be considered separately). The use of certified reference materials during method validation remains an imperative. Working personnel should be periodically trained. Well-trained and science-oriented analysts should be able to critically review and confirm their own results. Repetitive and sensitive analysis steps should be described clearly and in detail by means of standard operation procedures. One of the main objectives of the laboratory should be data traceability. In this respect, description of the applied methodologies with the mention of all relevant details, equipment status, and related information on its calibration and calculation procedures should be available. Error propagation studies are highly advisable for the entire analytical procedure, from sampling to results calculation. Participation in collaborative studies should be

considered in order to evaluate the overall quality of a given laboratory. Good laboratory practice guidelines should be interpreted in a positive, science-oriented way, focused on the awareness of the critical daily working problems. Whole activity should be oriented to ensure complete equivalence between good laboratory practices and good analytical practices, which do not necessarily mean the same thing.

The most common electrochemical procedures of pH evaluation are based on potentiometric measurements. The theoretically best described is the hydrogen electrode, consisting of platinum metal in contact with hydrogen gas but its use, however, is restricted to specialized laboratories. The various types of glass electrodes offer a wide pH range of dynamic response, which only at the ends of the pH scale may be subject to acid or alkaline errors. The glass electrodes are of various constructions, both macro and micro down to the micrometer scale. Most convenient for routine measurements are glass electrodes mounted in one body with the reference electrode. The uncertainty of electrochemical pH measurements is usually below 0.02 pH unit but may depend on the construction details of the cell. For special applications the glass electrode can be replaced by some metal/metal oxide electrodes, of which the antimony electrode is most commonly used. However, such sensing electrodes are more sensitive to the presence of redox species in the sample solution. Sensors that recently became more popular are those with polymeric membranes, containing a pH sensitive carrier such as tridodecylamine. Their use in nonaqueous media is often restricted, and their lifetime is often shorter than that of glass electrodes.

## Introduction

Pharmaceutical analysis is traditionally defined as analytical chemistry dealing with drugs both as bulk

drug substances and as pharmaceutical products (formulations). However, in academia, as well as in the pharmaceutical industry, other branches of analytical chemistry are also involved, viz. bioanalytical chemistry, drug metabolism studies, and analytical biotechnology. The development of drugs in the pharmaceutical industry is a long-term process, often taking more than a decade from the start of the research project to appearance of a drug on the market. That process involves several decision points, such as the choice of the candidate drug after the discovery phase, the application to the authorities before

testing the compound for the first time in humans, and finally the new drug application for marketing, which summarizes the data obtained from all the studies needed for approval of the drug as a medicine. In all these steps the amount of data generated is enormous. Analytical chemists are involved in many of the studies that constitute this documentation. Substance quality and its specifications are based on substance analysis, and that knowledge is later used for quality control (QC) of the substance during full-scale production. Product analysis involves dealing with the various formulations used for toxicological studies, clinical studies, and marketing. The results from such work lead to specifications that form the basis for the QC of the product. For both substances and formulations there is an increasing interest in the introduction of process analytical chemistry.

Biomolecules, i.e., macromolecules such as proteins or hormones, either produced by isolation from biological sources or by means of biotechnology, must also be subjected to careful analytical control. Thus, while the analytical tasks required for biomolecules are somewhat different from those of ordinary pharmaceuticals, when it comes to regulation and documentation of their quality and properties they definitely belong to the same group.

There are a number of regulations that have to be followed in the development of pharmaceuticals as well as in their production. Regulatory approval is required prior to each clinical trial and before marketing is licensed.

An important part of the development process is safety evaluation, primarily the toxicology tests, which run from 1 to 24 months in different species. During this time bioanalytical studies are performed as well as control of the formulations used in the tests. After approval for marketing the authorities exercise control of products on the market and require postproduction stability data. Public interest in the quality of drugs is also reflected in the compilation of substance monographs in compendia that are known as pharmacopoeias. In addition to collections of substance monographs, these pharmacopoeias contain general analytical methods and some also contain monographic requirements on the formulation of the substances.

This article provides an overview of mainly substance and product analysis (traditional pharmaceutical analysis), as used in the pharmaceutical industry. The support of other branches of analytical chemistry will be mentioned.

## Bulk Drug and Pharmaceutical Products

### Common Features

**Identity testing** Identity testing is used to verify that the drug substance is what it is stated to be, that a raw material is qualified, or that the formulation contains the correct compounds. Infrared (IR) spectra are used quite extensively in industry, whereas the pharmacopoeias often have a set of alternative tests. These can be color reactions, melting point of a compound or derivative, optical rotation values, or ultraviolet (UV) spectral data such as maximum wavelength and absorptivity. Today, chromatographic data are also used to support identity tests. Near-infrared (NIR) spectrometric methods are used increasingly for identity testing as no sample preparation is needed and it can be used in a noninvasive way, i.e., the container is left intact if made of glass or plastic.

**Impurities** Impurities or degradates require separation methods and are usually studied at the level from 0.05% to 2% (purity patterns) or from 0.1% to 5% (stability profiles). This means that the analytes have to be quantified in up to a 2000-fold excess of the major compound. In practice, qualitative work is performed at still lower levels. This sometimes creates problems in the chromatographic methods as minute amounts of related substances may be hidden under the peak of the drug itself. This was the background for the interest in peak purity tests, which, however, did not really get momentum, one reason being that a peak impurity present at below 1% may be difficult to detect. Also, peak purity tests are inferior to the use of complementary separation systems. Alternative liquid chromatography (LC) methods, gradient elution, or capillary electrophoresis (CE) are advisable instead. Today, sensitive nuclear magnetic resonance (NMR) detection online is a reality and can be used when other means fail.

**Selected analytes** Selected analytes sometimes have to be analyzed at parts per million levels. Typical examples are aromatic amines, nitrosamines, reactive intermediates left from the synthesis, or certain solvent residues, i.e., all components that are known to be noxious and thus must be controlled separately.

**Compendial analysis** Pharmacopoeias are the official collections of drug standards. They all include requirements for drug substances but only a few have monographs for products (formulations). Harmonization between the compendia for the three big

markets, Europe, Japan, and the US, is under way. There is an acceptance now that the major pharmacopoeias are, in principle, intended for the pharmaceutical industry and the authorities and not for community pharmacies as was the case earlier.

### Bulk Drug Analysis

**Physicochemical characterization** Physicochemical characterization yields a number of important parameters that can be used in the control of the quality of a substance. Typical properties are melting point and other thermal data, solubility, acid–base behavior with  $pK_a$  values, redox potentials, polymorphism, and spectral information. Other property-influencing parameters are choice of counterion and salification studies.

**Purity tests** Purity tests are, in particular, focused on related substances such as homologs, analogs,

by-products from the synthesis, or degradates. Enantiomeric purity is now a regular test requirement for chiral compounds. Chromatography is currently the most important check, giving essentially the fingerprint of a synthesis. An example of a separation of some potential impurities that have been added to a metoprolol sample is given in **Figure 1**. For qualitative studies LC–mass spectrometry (MS) is now established as the primary online analytical tool for the elucidation of unknown structures among the impurities. From a toxicological point of view, the impurity profile of the substance batch used in safety studies should form a reference for the full-scale production material. This means that in later batches impurities in amounts that exceed those found in the batches used for toxicology should be avoided. The high standard and good reproducibility required of the purity profile method is clearly

**Figure 1** (A) Separation by LC of metoprolol and some of its potential impurities that have been added in amounts from 0.01% to 0.4% to a pure sample. Peak 6, Metoprolol; peak 7, an unknown impurity. Peaks 1–11, see structures in (B). Column: 125 mm long and 4 mm ID filled with 5  $\mu$ m C-8 particles (Li Chrospher RP-Select B). Mobile phase: acetonitrile, 17% in ammonium phosphate buffer 0.05 mol  $l^{-1}$ , pH 3.2. Detection at 280 nm. (Reproduced with permission from Lars A. Svensson, Astra Hässle/AstraZeneca, Mölndal, Sweden.)

evident from that perspective. There are some other tests that also contribute to the general impression of the quality of a substance, i.e., tests for protolytic impurities, content of chloride, sulfated ash or residue upon ignition that gives the inorganic content. These tests reflect the performance of the purification process in general, but their importance will probably diminish in the future. For inorganic ionic analytes the older methods can be replaced by ion chromatography.

**Heavy metals and arsenic** Heavy metals are routinely determined, often with one or other form of sulfide precipitation. These compendial tests are performed from the viewpoint of safety and the general limits ( $1\text{--}30\ \mu\text{g ml}^{-1}\ \text{g}^{-1}$ ) are now more often related to the dose. For metals such as mercury, lead, cadmium, or nickel, atomic absorption spectrometry or other instrumental methods are often prescribed. Copper and other transition metals can act as catalysts in certain degradation reactions and thus require special attention. Arsenic tests that were important at the beginning of the previous century are now being phased out.

**Potency assay** Common for all bulk drugs is an assay of potency. This can be an aqueous or nonaqueous titration based on protolytic properties or on some other property. Many compounds lack functional groups suitable for titration and here separation methods (LC in particular) are often used. However, titrations are preferable as their precision is, in general, superior.

**Biomolecules** Biomolecules such as proteins represent a special type of bulk drug. Depending on the source, various chromatographic tests are used to show the absence of contaminating proteins remaining from the purification process. The separation methods used have a more biochemical character and differ from those for compounds of synthetic origin. Immunochemical techniques are very often used as complements. Typical tests include separation of dimers, trimers, etc., from the biomolecule itself. Molar mass determination by size-exclusion chromatography (SEC) is common and is strongly supplemented by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS).

Biotechnological products have some advantages over products from human or animal origin with respect to the risk of transferred diseases, but they also have some special requirements. In particular, when parenteral use is intended, the absence of host proteins has to be guaranteed as well as DNA residues

from the vector used for expression. Such matters often need the attention of specialist laboratories.

**Bioassay** Many biomolecules have, over the years, been assayed using methods where biological activity in an animal, organ, or receptor is assessed, i.e., a bioassay. The traditional opinion has been that such bioassays cannot be replaced by physicochemical methods as the latter do not reflect the biological activity. Bioassays, no matter how well characterized they are, have certain disadvantages with respect to precision, time, and cost compared to instrumental methods. The pharmaceutical industry has therefore been able to show that, for several of its biotechnological products, e.g., insulin and human growth hormone, chromatographic methods (LC in particular) can give the same information. Moreover, proteins from different species can be chromatographically separated and degradation products well quantified. This is not possible in quantitative bioassays where only the sum of activities is obtained. A similar paradigm shift has also taken place for antibiotics, where LC methods give information not available from microbiological assays. However, it should be noted that for many biomolecules there are, as yet, no alternatives to bioassay.

**Excipients** There are a great number of materials that are used to transform a substance from an active compound to a medicine useful for a patient in a therapeutic situation. These materials, or excipients, are becoming more important in the construction of modern drug delivery systems. Many excipients are macromolecules and have been used for decades in traditional remedies. With modern drug delivery systems the old requirements may not always fit those necessary for the technologically advanced products of today. This has become increasingly evident in recent years. Moreover, the requirements on excipients in the various pharmacopoeias are not always consistent with each other and are often rather vague. This has been recognized at an international level and efforts at harmonization are proceeding. Polymeric excipients are generally characterized by some average physicochemical property such as viscosity. Studies of the distribution of molar mass have seldom been performed on such excipients due to the lack of suitable methods. However, with SEC in online combination with light scattering (e.g., MALS, multi-angle light scattering) and refractometric detection it is now possible to determine the molar mass distribution directly without any standard calibration procedure. A nice example is given in **Figure 2**. The majority of the excipients used today, however, have molar masses

**Figure 2** The molar mass distributions of two hydroxypropyl-methyl cellulose (HPMC) batches (Metolose 60 SH 10 000 cps, Shin-Etsu, Tokyo, Japan) determined with SEC connected online to multi-angle scattering (MALS) and refractometric (RI) detectors. The broad distributions contain HPMC chains ranging from a few thousands up to several millions in molar mass. Despite the fact that the two batches belong to the same viscosity grade, significant differences are seen in the molar mass distributions. This emphasizes the importance of proper characterization of the complete molar mass distribution instead of only estimations via viscosity averages. (Reproduced with permission from Bengt Wittgren, Analytical Development, Astra Hässle/AstraZeneca, Mölndal, R&D Mölndal.)

in the same range as the active compounds. The tests for safety and purity are then similar to those of the drugs.

Excipients could usefully be classified or tested according to their properties at three levels, viz. molecular, particulate, and bulk properties. Those are tested for by the manufacturer of a dosage form. It is not clear which of those properties should be covered by the official compendia. Testing of functionality, i.e., at particulate or bulk level, does not seem to be possible yet. Typical tests are bulk density, specific surface area, flowability, and particle size distribution. However, the standardization of methodology in compendia, without specification limits, will probably be of help for both vendor and buyer. Therefore, functionality related tests are now being proposed in the pharmacopoeias. As excipients are getting more complex, their analytical characterization is very important. Interesting opportunities lie ahead, particularly with macromolecular separation, MALDI-TOF-MS, and spectrometric methods such as NIR.

### Pharmaceutical Products

A medicine is much more than simply a drug substance, and huge efforts are put into the development of biopharmaceutically optimized drug delivery systems. Analytical chemists contribute to that process by analyzing the experimental formulations with respect to various properties such as homogeneity, content, stability, and release of the active agent in dissolution testing but also through bioanalysis to

create data for *in vitro*–*in vivo* correlations. In particular, stability has to be monitored over the entire test period.

**Solid dosage forms** Solid dosage forms, e.g., tablets and capsules, are by far the most common for several reasons. The production of relevant doses is easy to accomplish, and scale-up is usually a standard technological process. All divided dosage forms have strict requirements for uniformity of content, i.e., a statistical sampling of the batch should show a uniform distribution of the active component. This requirement is especially important for units with very small amounts of the active component, i.e., from a few micrograms per dose to 50 mg. This has often led to automated analytical methods to cope with the large number of samples.

The pharmacokinetic performance of a drug influences the construction of a formulation. This has nowadays led to a dominance of drug delivery systems that provide a controlled or modified release of the drugs, defined as extended or delayed release. Release-controlling polymers are used to build up a barrier that prevents immediate release of a compound. In this way high peak plasma concentrations of drugs are avoided and usually only one dose per day is necessary. The characteristic properties of the formula are evaluated in *in vivo* tests where blood samples are analyzed often by extremely sensitive bioanalytical methods.

However, for routine QC it is usual to rely on *in vitro* models, which obviously should be correlated with the *in vivo* data. Dissolution testing has been standardized in the pharmacopoeias for a long time with respect to release media, apparatus, and other conditions. However, in modified release formulations the prescribed conditions might have to be changed. This is the responsibility of the analytical chemist, whilst still having the routine testing conditions in mind, i.e., QC methods should also be practically feasible.

**Parenterals** Parenterals are dosage forms intended for injection into the body. Water is normally used as the solvent. The special tests for parenterals include sterility and absence of particles as well as endotoxins that can give fever reactions. The old test that was performed on rabbits is nowadays often replaced by a test based on the reaction of endotoxins with a lysate from *Limulus amoebocyte* (LAL test), which is less time consuming and more exact. Sterility testing is complicated from a sampling point of view because of the random appearance of microbial contaminants. A thorough in-process validation is the best way to ensure that the products are sterile. In large

volume, parenterals' requirements on limits for particle contamination have created a need to analyze for particles down to the size of a few micrometers, usually by light blocking or by conductivity techniques. For compounds that are sparingly soluble in water other solvents or cosolvents can be used creating problems of quite a different kind for both formulator and analyst, such as evaluation of precipitation phenomena and interactions with packaging materials. For freeze-dried (lyophilized) products the reconstitution properties have to be controlled.

**Other dosage forms** Other dosage forms are needed for topical administration such as creams, ointments, and patches. The latter should usually deliver the drug over an extended period of time and thus require reliable *in vitro* release testing and as a consequence also *in vivo* data.

Sometimes other routes of administration are necessary. Thus, suppositories are used for rectal delivery and sprays for the nasal route. Sublingual delivery can be advantageous, e.g., for nitrate esters. For asthma the use of inhalators has increased considerably as reliable hi-tech delivery systems have been developed. Here, the uniformity of the inhaled dose (usually a few micrograms), as well as the narrowness of the particle size distribution, must be safeguarded.

The analytical problems of these dosage forms have to do both with the type of excipients used and their characterization and quality as well as the function of the delivery system.

**Toxicological formulations** Toxicological formulations appear in the early project work in short-term toxicology tests performed before testing in humans and later on during long-term carcinogenicity studies before approaching the authorities for marketing approval. The reason for mentioning them here is that at this early stage a full understanding of the properties of a drug is not always available, and, most important, the animal feed into which the drug may be blended, is a very difficult matrix in which to analyze a drug. Yet, the analyst has to determine the homogeneity and the stability of such formulated animal feeds during the use of the material. Here the rules of Good Laboratory Practice (GLP) are emphasized including validation of analytical methods.

**Packaging materials** Packaging materials are also part of the medicine presented to the patient. They are usually polymers that have properties chosen to give the drug product protection during storage and handling. Usually multilayer materials are used, as in blister packages for tablets, with some layers being a barrier toward moisture penetration.

Plastic bottles are becoming more common now. For many products, particularly parenterals, there is a risk of interaction between the polymeric material and the active component, especially if the latter has a lipophilic character. Rubber stoppers in parenterals are likewise prone to trap organic molecules from, and also leak stabilizers into, the solution. Biomolecules in solution may adsorb onto these surfaces and this may be especially significant if the amounts in solution are minute. From these comments it is clear that stability testing must also be performed in the consumer package under appropriate conditions of temperature, humidity, and light.

**Stability studies** Stability studies constitute a major task for the analytical chemical laboratory. The aims of initial physicochemical studies and investigations of incompatibilities, i.e., preformulation studies, are to identify the weak points of a compound, in order to avoid vulnerable conditions in the formulation. An example of an incompatibility reaction in a formulation containing three active ingredients and stored under accelerated conditions is given in Figure 3. The structure of the degradate was elucidated with electrospray LC-MS and verified as shown in Figure 4. Heat, moisture, oxygen, and light may all influence stability.

Tests have to be performed under standardized conditions with respect to temperature and humidity. Accelerated tests can be used to identify the weak points, but in the documentation submitted to the authorities long-term stability data under normal conditions are required. In these studies stability

**Figure 3** Separation by LC of degradates from a formulation containing hydralazine. After storage at accelerated conditions components A and B started to grow the peaks. They were both the result of an incompatibility with lactose. The structure of B was elucidated by LC-MS as shown in Figure 4. (Reproduced with permission from Rose-Marie Janson, Astra Hässle/AstraZeneca, Mölndal, Sweden.)

**Figure 4** Mass spectra of degradate B in **Figure 3**. Electrospray LC–MS was used with a 0.5 m fused silica capillary column, ID 250  $\mu\text{m}$ . The packing material was 5  $\mu\text{m}$  C-18 Chromasil and the mobile phase was 60% acetonitrile in 5  $\text{mmol l}^{-1}$  ammonium acetate with a flow rate of 15  $\mu\text{l min}^{-1}$ . The left-hand panel mass spectrum was obtained with the mobile phase consisting of water and the right-hand panel with the use of heavy water (deuterium oxide) instead. The mass number difference is due to nine hydrogen atoms exchanged with deuterium plus the ion charge  $\text{H}^+$  being changed to  $\text{D}^+$ . (Reproduced with permission from Karl-Erik Karlsson, Astra Hässle/AstraZeneca, Mölndal, Sweden.)

indicating assays are important and usually LC is the method of choice as the measurement of the drug content should not be disturbed by interfering components. Early degradation is, however, more reliably monitored through the degradates as the precision in the determination of a degradate is less demanding than the measurement of the corresponding decrease in the parent compound.

**Full-scale production and process analytical chemistry** Full-scale production is the final step in the research process. Scaling up from the pharmaceutical development laboratory via the pilot plant to full-scale production is not without problems. This is one of the reasons for the requirement by the authorities that stability studies should be performed and reported for the first three production batches. The transfer (scaling up) can be facilitated by thorough process controls that give an understanding of those parameters that must be controlled. Such efforts should start at least at the pilot plant scale and pave the way for the transfer to full scale. As pharmaceutical formulations are more complicated today than ever before, it is clear that process analytical chemistry/process analytical technology can

play an important role in the scaling-up procedure. In this way, it is possible to control the process by feedback reactions before severe deviations occur. Noninvasive techniques such as NIR and Raman spectrometry will be important. Probes with laser-based spectrometry also provide interesting possibilities in this context. Multivariate analysis for evaluation is a prerequisite for the success. If process analysis is utilized from the early formulation batches, many surprises will be avoided during scale-up and the production will be more reliable in quality and hence will be economical.

## Specifications and Quality Control

### Specifications

The quality requirements of a substance in bulk and those of a pharmaceutical formulation are compiled in specifications. In these documents the requirements on the various quality parameters are given as minimum or maximum limits or ranges. Formulations often have requirements on technical properties such as dissolution rate, disintegration, and hardness for tablets. All those requirements are the result of

comprehensive studies in the R&D phase, where the knowledge of the properties of the drug is gathered, resulting in the optimized formulation of the active component. The analytical and technical test methods that are linked to the specifications will have evolved during the R&D process and can, before the new drug application stage, be transferred to QC laboratories.

It is important to bear in mind that what is used in clinical trials should be reproduced in full-scale production. Of special importance is the particular batch, which is studied *in vivo* and compared with *in vitro* properties as in dissolution testing to establish an *in vivo*–*in vitro* correlation. This batch is of critical importance for the future and its documentation has to be thorough. The bioavailability, as documented in this batch, is the foundation for the coming market presentation. Equally important are the substance batches used in safety studies, and requirements on the knowledge of their quality are very exacting. The requirements at release can be somewhat tighter than those at a control performed any time during the entire lifetime of a medicine.

### Reference Substances

Most methods require some form of chemical reference substances (CRS), which have been characterized and presented in a regulatory submission more thoroughly than according to normal specifications, for example, by adding thermoanalytical data and spectrometric data for structural evidence, e.g., IR, NMR, MS, and UV. Compendial methods have official CRS, which are available for customers all over the world. It is important to remember that a reference substance can be used for different purposes, not all of them requiring extensive testing. So a CRS for identity testing is less demanding from a purity point of view. For daily work a less expensive working standard can be calibrated versus a CRS.

### Quality Control

Full-scale production is checked in the QC laboratories according to the specifications and test methods approved by the authorities. Decisions by QC management cannot be overruled by any person in the organization, which puts a particular onus on the competence and judgment of the person in charge of QC. In addition to the chemical and biological tests that comprise QC the organization can introduce preventive measure to avoid quality impairment. This activity is defined as integrated or total QC and is further outlined in Good Manufacturing Practice (GMP). It cannot be emphasized enough that chemical control at the end of a process can never replace

high standards in the process itself. This is sometimes so evident that release in certain cases can be given based on the documentation and control in the process steps. This is called parametric release. Parametric release has been accepted by the authorities in those cases where end control does not fully reflect failures in the production. This has been most evident in many biotechnological processes, where the absence of host proteins, DNA residues, or virus particles has been approved through a thorough validation procedure where the purification step is challenged. The analytical methodology is not adequate in this situation at the end control. Process analytical chemistry will in the near future play a similar role in showing that a process does not run beyond prescribed limits. This not only gives better quality in products, but also fewer failures and thus reduced costs.

Verification of identity is required at several stages during the process, not only at the end. This can be done in many ways and it is important to remember that the sum of the tests performed during a process also contributes to that verification. Biotechnological products are a special case in that the identity of the recombinant protein with that of the native one has to be established. Thus, it is important that the correct order of the sequence of amino acids is verified. Peptide mapping has been one way of showing this by comparing the chromatographic pattern of peptide fragments obtained after enzymatic cleavage. CE complements LC in this role. In this area, MS techniques will complement peptide mapping as MS will allow molecular ions to be determined up to and above 200 kDa.

### Regulatory Aspects

GMP was mentioned above and has been a cornerstone of pharmaceutical production and control since the 1970s. These regulations state clearly what has to be done to safeguard quality from the beginning of the production process to the end, viz. documentation, staff qualifications, standard of facilities, technical standards, handling of material, labeling, equipment, etc. GMP is valid for production and R&D, such as in validation studies, technology transfer, stability studies, clinical trial material release. The rules also state that all documentation of analytical methods should fulfill certain performance criteria, that instruments should have maintenance records, and that their performance and those of the method should be documented. GLP is the term used in safety studies for this kind of documentation and validation and is similar to GMP but differs in details.

### International Harmonization

Harmonization of requirements has successfully been made by the International Conference on Harmonisation (ICH), e.g., in guidelines on stability documentation, method validation, and investigation of impurities. Regarding impurities information is given on how the limits should be set and at what level identification is needed. Similar efforts are seen for dissolution testing and how to correlate *in vivo* and *in vitro* data. The question of bioavailability and bioequivalence is an important one and has been dealt with as well. As a consequence of the rapid development in chiral separations we can now see a harmonization of requirements also for chiral drugs.

### Validation of Analytical Methods

Validation of an analytical method establishes in laboratory studies that the performance characteristics of the method meet the requirements for the intended application, thus the method does what it is expected to do. The following items are listed by ICH: precision, accuracy, limit of detection, limit of quantification, specificity, range, linearity, and ruggedness. Of these, accuracy is probably the most difficult to document or obtain, at least for solid formulations. This has to do with the fact that recovery experiments are difficult to design in such a way that they resemble the process conditions. The reactions there can create interactions that are not obtained in an experiment where the analyte has only been mixed or spiked to the sample.

Specificity, or selectivity as recommended by IUPAC, is the factor in the validation process that is most often discussed. Selective methods are required in a product release specification, which means that a chromatographic procedure often has to be carried out but sometimes a simple UV method is sufficiently selective and thus free from interferences. Here cost-effectiveness should be the guide and analysts should therefore use their scientific arguments to justify using the simpler method. Validation procedures are equally important in the documentation of bioanalytical methods.

### Emerging Techniques in Pharmaceutical Analysis

Analytical chemistry is one of the disciplines most frequently involved in the R&D work performed in the pharmaceutical industry. This makes the industry very analysis intensive, which explains the high level of interest in testing new methods in order to get further information. It is also clear that this interest in learning, and using the latest techniques, stems

from a desire to obtain reliable information more quickly, or to obtain complementary data.

The research process is a long-term commitment and requires high standards in the results from the very beginning. The quality of the results relies on competent analytical chemists, but also on the availability of good instrumentation, which is often evident in the laboratories of the research intensive pharmaceutical industry. Separation techniques, especially LC, have had an enormous impact on pharmaceutical analysis. The combination of LC with MS has now extended the possibilities of the techniques as qualitative and quantitative data can be obtained online. The availability of less-expensive bench-top instruments operated by nonspecialists has changed the situation considerably.

The development of new techniques usually proceeds in a stepwise fashion and, at present, mass spectrometric techniques are taking a giant step toward the analysis of macromolecules in a reliable way. This revolutionary process now shows promising results with molar masses of more than 200 kDa being determined using TOF techniques. Possibilities to combine them online with separation methods are at hand. These MS extensions have great impact on biotechnology products and macromolecular compounds used as excipients. Another area where rapid development is taking place is Raman spectrometry. New technology has opened interesting possibilities for this old technique. Many opportunities lie ahead, not least in imaging techniques, both in regular and in in-process analysis.

Separation methods will see continued growth, particularly the capillary techniques. Capillary chromatography is particularly useful when expensive mobile phases are used. A good example of LC-MS using packed fused silica columns 250  $\mu\text{m}$  in diameter is given in **Figure 4**. Here, heavy water was used interchangeably with an aqueous phase. Hydrogens bound to heteroatoms (O, N, S) were then replaced with deuterium, which was easily revealed in the mass spectrometer. This tells the analyst how many labile hydrogens the molecule has (in the case of the example this was 10). For macromolecules up to particles, the use of field-flow fractionation techniques is approaching broader acceptance. Further development of matrix-forming agents will take place that will facilitate the use of MALDI-TOF-MS for other classes than proteins, i.e., carbohydrate-based polymers. CE is an excellent complement to LC, not least for biotech applications and the technique can be used in QC laboratories as well. Capillary electrochromatography has not come that far yet but can deliver separations with impressive efficiency. Supercritical fluid chromatography (SFC)

with packed columns has mainly been used for chiral separations, one reason being the easy transfer of conditions to the semipreparative scale for fast isolation of enantiomers. An example of a rapid chiral separation is given in Figure 5. One limiting factor with SFC is that CO<sub>2</sub> can react with primary and secondary amines. However, it has now been shown with SFC–NMR that with a little steric hindrance at the nitrogen this reaction will not take place. NMR-based methods will be more common, with and without previous separations. LC–NMR is now a frequently used technique. With solid-state NMR valuable information on powder properties can be obtained. Circular dichroism in detection of chiral compounds can provide information on which isomer is at hand.

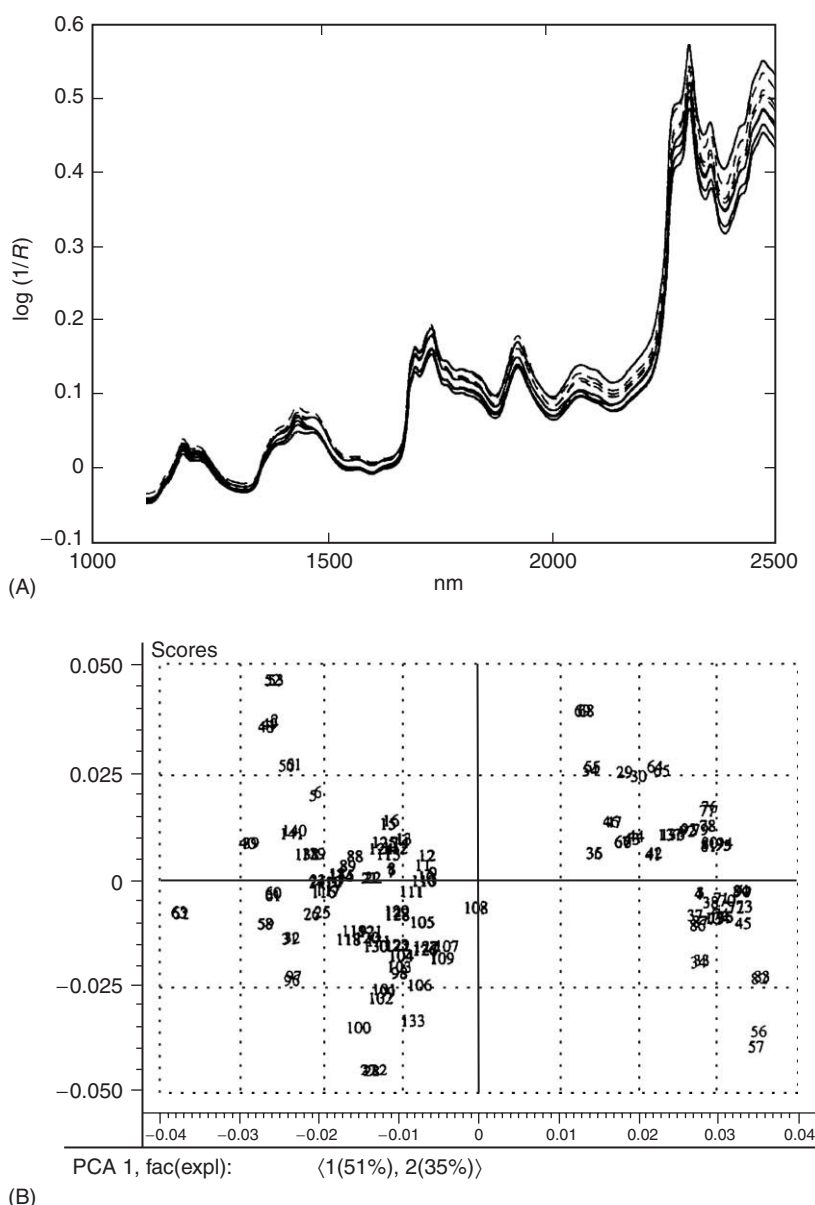

Chemometric methods, in particular multivariate analysis, have an impact on many types of techniques, especially when large amounts of spectral data are collected, and in areas where specific properties that are not easily measurable (such as taste, texture) have to be correlated with physicochemical

parameters. In this context, NIR has gained prominence within the pharmaceutical industry. An example from the analysis of a number of cellulose ether samples with reflective NIR is shown in Figure 6. The individual spectra do not show much in the way of differences. The spectra were corrected for different light penetration depths by multiplicative signal correction. Then, the entire spectra were projected by principal components analysis as points on a plane. The samples could be grouped into two clusters in this plane, one for each vendor. The calibration of this technique is entirely dependent on multivariate analysis or chemometrics and this combination grows in use. In the same way process analytical chemistry is heavily based on multivariate data. Many noninvasive approaches rely on NIR and multivariate calibration. New approaches combined with techniques that will stand harsh process conditions are also introduced, e.g., in process analytical applications. In the near future we will probably see applications in the pharmaceutical analytical field based on nanotechnology or lab on a chip and

**Figure 5** Fast SFC analysis of the *S*-enantiomer of clevidipine after hydrolysis into its corresponding acid. Column and conditions: Chiralpak AD 50 × 4.6 mm ID at 30°C, mobile phase carbon dioxide with 28% of 2-propanol, flow rate 4.0 ml min<sup>-1</sup>, backpressure 150 bar, UV detection at 240 nm. Sample preparation and work-up: 2 mg of *S*-clevidipine substance was dissolved in 0.5 ml of methanol followed by 50 μl of 1 mol l<sup>-1</sup> sodium hydroxide. After 10 min, 1 ml of water and 50 μl of sulfuric acid, 1 mol l<sup>-1</sup>, was added and 0.5 ml of dichloromethane as extraction medium. After brief vortexing and centrifugation 5 μl of the lower organic phase was loaded manually and injected. Upper trace sample, lower trace sample with ~0.1% of *S*-acid added. (Reproduced with permission from Gyllenhaal O (2001) Fast enantioselective separation of clevidipine and a dihydropyridine substituted acid by SFC on Chiral pak AD. *Fresenius' Journal of Analytical Chemistry* 369: 54–56; Springer.)

**Figure 6** (A) Reflectance spectra in the near-IR of a number of ethyl celluloses obtained from two vendors. (B) Principal component projection of the spectra in (A) after multiplicative signal correction. The left cluster is from vendor A and the right one from vendor B. (With thanks to Mats Josefson, Astra Hässle/AstraZeneca, Mölndal, Sweden.)

laser-based spectrometry that will open new possibilities to reveal conditions in the products during various stages of production. Clearly, in the future new principles of measurement may also be necessary and the analytical chemist will have much to contribute here.

## Drug Purity Determination

**P M Lacroix**, HPFBI Laboratory Programme, Ottawa, ON, Canada

Canadian Crown Copyright © 2005, Published by Elsevier Ltd. All Rights Reserved.

### Introduction

The purity of a drug and the determination of the nature and quantity of any impurities present are key questions for the modern pharmaceutical analyst. The nature and quantity of impurities in a drug product depend on the route of synthesis used to produce the drug raw material, purification procedures, dosage form, manufacturing and formulation, and the conditions under which it has been stored.

Impurities in reagents or starting materials may be carried through the synthesis intact or react to produce new impurities. By-products may be formed at various stages of the synthesis resulting in compounds with substitution at other sites or the formation of alternate ring systems. These by-products, in turn, may react in subsequent steps. Reaction residues such as reagents, solvents, catalysts, or unreacted precursors of the drug may remain as impurities. Nonstereospecific reactions may give rise to drug isomers. Undesirable polymorphs of the drug may be formed during recrystallization. Impurities may also result from drug degradation, particularly in formulations, or under certain conditions of light, heat, humidity, or acidity.

The terms process contaminants and related substances are commonly used when referring to impurities. A related substance is a compound that is chemically related to the drug, arises from the manufacturing process, or forms upon storage. It may be a starting material, synthetic intermediate, or degradation product. A process contaminant is an identified or unidentified impurity that may be introduced during the manufacturing or handling, but excludes related substances and water. Examples of process contaminants include inorganic compounds (heavy metals, and ions such as chloride or sulfate), reagents, and solvents.

### Types of Impurities and Purity Specifications

To ensure the quality, safety, and efficacy of pharmaceutical products, most nations have enacted laws and regulations governing the production, manufacturing, import, and sale of drugs. Many countries, the Council of Europe, and the World Health Organization (WHO) have established pharmacopoeias containing specifications for drugs, including purity, and the methods of analysis that must be used to verify that these specifications are met. Examples of pharmacopoeias include the Japanese Pharmacopoeia (JP), the British Pharmacopoeia (BP), the United States Pharmacopoeia (USP), the European Pharmacopoeia (EP), and the International Pharmacopoeia (IP).

The USP defines five types of impurities: foreign substances, toxic impurities, concomitant components, signal impurities, and ordinary impurities.

Foreign substances are adulterants or contaminants that do not result from the synthesis or manufacturing process. Depending on the nature and concentration of the foreign substance, it may or may not be detected using the pharmacopoeial method. A drug found to contain a foreign substance would not meet compendial standards.

Toxic impurities are those that have a significant undesirable biological activity even at low concentrations and require identification and quantification by specific tests. They may arise from the synthesis, preparation, or degradation of the drug. An example of a toxic impurity is amphetamine hydrochloride in phenylpropanolamine hydrochloride, which the USP limits to 0.001%.

Concomitant components are not regarded as impurities but merely as a normal component of the drug. They may be compounds extracted along with a drug that is a natural product, for example, 17- $\alpha$ -hydroequilin, 17- $\alpha$ -oestradiol, and 17- $\beta$ -dihydroequilin in conjugated estrogens derived from equine urine. Concomitant components also include the inactive isomer of a drug administered as a racemic mixture

### Introduction

The purity of a drug and the determination of the nature and quantity of any impurities present are key questions for the modern pharmaceutical analyst. The nature and quantity of impurities in a drug product depend on the route of synthesis used to produce the drug raw material, purification procedures, dosage form, manufacturing and formulation, and the conditions under which it has been stored.

Impurities in reagents or starting materials may be carried through the synthesis intact or react to produce new impurities. By-products may be formed at various stages of the synthesis resulting in compounds with substitution at other sites or the formation of alternate ring systems. These by-products, in turn, may react in subsequent steps. Reaction residues such as reagents, solvents, catalysts, or unreacted precursors of the drug may remain as impurities. Nonstereospecific reactions may give rise to drug isomers. Undesirable polymorphs of the drug may be formed during recrystallization. Impurities may also result from drug degradation, particularly in formulations, or under certain conditions of light, heat, humidity, or acidity.

The terms process contaminants and related substances are commonly used when referring to impurities. A related substance is a compound that is chemically related to the drug, arises from the manufacturing process, or forms upon storage. It may be a starting material, synthetic intermediate, or degradation product. A process contaminant is an identified or unidentified impurity that may be introduced during the manufacturing or handling, but excludes related substances and water. Examples of process contaminants include inorganic compounds (heavy metals, and ions such as chloride or sulfate), reagents, and solvents.

### Types of Impurities and Purity Specifications

To ensure the quality, safety, and efficacy of pharmaceutical products, most nations have enacted laws and regulations governing the production, manufacturing, import, and sale of drugs. Many countries, the Council of Europe, and the World Health Organization (WHO) have established pharmacopoeias containing specifications for drugs, including purity, and the methods of analysis that must be used to verify that these specifications are met. Examples of pharmacopoeias include the Japanese Pharmacopoeia (JP), the British Pharmacopoeia (BP), the United States Pharmacopoeia (USP), the European Pharmacopoeia (EP), and the International Pharmacopoeia (IP).

The USP defines five types of impurities: foreign substances, toxic impurities, concomitant components, signal impurities, and ordinary impurities.

Foreign substances are adulterants or contaminants that do not result from the synthesis or manufacturing process. Depending on the nature and concentration of the foreign substance, it may or may not be detected using the pharmacopoeial method. A drug found to contain a foreign substance would not meet compendial standards.

Toxic impurities are those that have a significant undesirable biological activity even at low concentrations and require identification and quantification by specific tests. They may arise from the synthesis, preparation, or degradation of the drug. An example of a toxic impurity is amphetamine hydrochloride in phenylpropanolamine hydrochloride, which the USP limits to 0.001%.

Concomitant components are not regarded as impurities but merely as a normal component of the drug. They may be compounds extracted along with a drug that is a natural product, for example, 17- $\alpha$ -hydroequilin, 17- $\alpha$ -oestradiol, and 17- $\beta$ -dihydroequilin in conjugated estrogens derived from equine urine. Concomitant components also include the inactive isomer of a drug administered as a racemic mixture

but for which only one optical isomer has biological activity. An example of such a drug is atenolol for which the  $\beta$ -adrenoreceptor blocking activity resides mainly in the *S*-(–)-enantiomer.

Signal impurities are compounds that provide key information on the synthesis or degradation of the drug and require identification and quantification by specific tests. 4-Epianhydrotetracycline is a signal impurity that provides information on the degradation of tetracycline. The USP has set a limit of 2.0% on this impurity in tetracycline raw material.

Ordinary impurities are considered innocuous in that they have no significant undesirable biological activity at or below the specified limits. These impurities arise from the synthesis, formulation, or degradation of the drug. The USP monograph for glycopyrrolate contains a thin-layer chromatography (TLC) test for ordinary impurities for which the limits are 0.5% for individual impurities and 2.0% for the total of all impurities.

Impurities are typically resolved from the drug by a chromatographic procedure and quantified by comparison to an external standard, often the drug itself, rather than by comparison to standards of the individual impurities. Pharmacopoeial methods must be suitable for pharmaceuticals produced by different manufacturers that may contain different types and amounts of impurities. Pharmacopoeias typically view 1.0–2.0% as the general limit for total ordinary impurities, unless there is documentation to support a higher or lower level. Concomitant components, toxic or signal impurities are not included in the estimate of ordinary impurities and separate limits may be set for these, as necessary.

Individual ordinary impurities in drug raw material are typically limited to 0.5% or less. Many regulatory agencies require manufacturers to identify impurities present at levels of 0.1% or greater. If the structure is similar to that of a known carcinogen, mutagen, or other hazardous compound, toxicological and pharmacological data will be required prior to approval. Factors that are considered when establishing impurity limits are: toxicity, the costs involved in the cleanup procedure, and what levels can be expected when Good Manufacturing Practices are in place.

Pharmacopoeial methods reflect the state of knowledge of a particular drug at the time of publication. As more knowledge is gained, the need to revise existing methods or develop new ones may arise. For example, the existence of new impurities formed as a result of a different route of synthesis may come to light or, alternatively, better analytical techniques may be developed. Thus, modern pharmacopoeias have ongoing revision procedures.

*Pharmacopoeial Forum* (PF) and *Pharmeuropa* are USP and EP publications, respectively, and contain proposed monograph revisions, new monographs, and articles on other compendial matters. The purpose of these publications is to make proposed changes available for public comment before they become official.

In 1990, the International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) initiated a process involving both regulators and industry as partners in scientific and technical discussions on harmonization of testing procedures required to ensure and assess the safety, quality, and efficacy of medicinal products containing new drugs.

The six parties that are the founding members of ICH and directly involved in the decision-making process represent the regulatory bodies and the research-based industry in the European Union, Japan, and the USA, the three regions where the majority of new drugs are developed. They are: the Committee for Proprietary Medicinal Products of the European Agency for the Evaluation of Medicinal Products and the European Federation of Pharmaceutical Industries and Associations in the EU, the Ministry of Health, Labour and Welfare and Japan Pharmaceutical Manufacturers Association in Japan, the Food and Drug Administration and Pharmaceutical Research and Manufacturers of America in the USA.

A number of ICH guidelines have been published and are now at step 5, which means that the final draft has been signed by the three regulatory agencies and it is incorporated into regional guidelines or regulations. These include: Impurities in new drug substances (1995), Impurities in new drug products (1996), Impurities: Guideline for residual solvents (1997), Text on validation of analytical procedures (1994), and Validation of analytical procedures: Methodology (1996).

The ICH guidelines on impurities apply to new drugs only and several classes of drugs are excluded, for example, biological or biotechnological products, radiopharmaceuticals, herbal products, and crude products of plant or animal origin. Drug substance impurities are classified as organic, inorganic, and residual solvents and drug product impurities are defined as degradation products. Polymorphs, enantiomeric impurities, and foreign contaminants are not covered in the impurity guidelines. Organic impurities are generally related to the synthesis of the drug substance or may arise during storage and include starting materials, by-products, intermediates, degradation products, and materials used in the synthesis, such as reagents, ligands, and catalysts. Inorganic impurities are generally related to the

synthesis and may include heavy metals, inorganic salts, reagents, ligands, catalysts, and process materials such as filter aids or charcoal that remain in the final drug substance. Residual solvents are organic or inorganic liquids that are used in the manufacturing process and remain in the final drug substance.

The ICH guidelines on impurities set requirements for the reporting, identification, qualification, and control of impurities. Qualification is the process of acquiring and evaluating data that establishes the biological safety of an individual impurity or a given impurity profile at the level or levels specified. Specified impurities are identified and unidentified impurities expected to be present in the new drug substance and new drug product over the period of intended use and under recommended storage conditions. Specified impurities should be individually listed in the specifications.

## Methods and Techniques for Drug Purity Determination

### Methods

Factors to consider in the choice of an analytical method for a pharmaceutical product include the chemical and physical nature of the drug and its impurities, the matrix in which it exists, the purpose of the analysis, and the analytical performance required. Different methods may be necessary to quantify impurities with different physicochemical properties.

Impurity levels are frequently controlled by limit tests based on TLC. A standard, either the drug itself or an impurity, is applied to a TLC plate at a level corresponding to the limit for individual impurities, and used for comparison purposes to impurity spots observed in the chromatogram of a test sample developed on the same plate. There is usually a requirement that no spot in the test chromatogram be more intense in color than the spot corresponding to the standard.

For semiquantitative tests, the level of each impurity in the test solution is estimated by comparison to a series of concentration levels of standard solution applied to the same plate.

Quantitative tests provide an estimate of the concentration of a specific impurity. This type of test is normally required for the determination of signal or toxic impurities and is used with increasing frequency for ordinary impurities. Quantitative tests are based on techniques that provide a high degree of accuracy and precision such as gas chromatography (GC) and liquid chromatography (LC).

### Method Development

The development of methods for purity determination requires knowledge of the structure and other properties of compounds likely to be present as impurities. Potential impurities may be postulated from a review of the routes of synthesis of the drug. These compounds, and others, may be isolated from mother liquors or drug raw materials that have been degraded under stressed conditions. In some cases, impurities may be commercially available. Information on the chemical and physical properties of impurities is helpful in selecting the technique and type of method for detection and quantification. Some of the properties examined include: solubility, stability, absorbance in the ultraviolet (UV) or visible range, pH, and melting and boiling points.

The performance of a method is expressed in terms of its specificity, sensitivity, accuracy, precision, detection and quantification limits, linearity, range, robustness, and ruggedness. In addition to the parameters listed above, other factors to be considered are simplicity and cost. The latter may be of less importance for methods used at the product development stage or for regulatory analysis but may be of considerable importance for routine quality control methods.

During method development, the analyst must try to build safeguards into the method to ensure reproducibility. This can be achieved, for example, by using well-defined reagents or columns for chromatography, using suitably qualified equipment, and designing a proper system suitability test. System suitability tests are usually included in all pharmacopoeial LC methods. They may include requirements for the resolution of two compounds, retention times or capacity factors, tailing factor, column efficiency, or precision of the system. They are a measure of the suitability of the entire system, hardware, electronics, and solvents, to carry out the analysis. An analysis should be carried out only when the system suitability requirements can be met. It provides a means of ensuring good results without having to validate the method again.

### Method Validation

Validation is the process by which a method is tested and shown to be effective for its intended purpose. The type of method will determine which analytical parameters are to be evaluated and how these can be measured. The definitions provided below correspond to those contained in the ICH guidelines on method validation.

Specificity, according to the ICH definition, is the ability of the method to measure the analyte

accurately in the presence of other compounds expected to be present in the sample matrix. This corresponds to the International Union of Pure and Applied Chemistry (IUPAC) definition of selectivity; according to the IUPAC, specificity is the ultimate in selectivity, meaning that no interferences are supposed to occur. For related substances methods, the individual impurities must all produce a response within a reasonable time frame and be resolved from the drug and the solvent front. For nontoxic impurities, it is preferable, though not absolutely necessary, that they be resolved from each other. In order to be able to demonstrate the specificity of a method, the analyst normally requires standards of each of the possible related substances. Should a new impurity become available after a method is developed, it would be necessary to revalidate the method by showing that this impurity is resolved from the drug and can be suitably quantified.

Accuracy is the closeness of a measured value to its true value. Although it may not always be possible to determine the accuracy of a method, results from different types of methods can sometimes be compared. When making these comparisons, it is important to keep in mind the limitations of the methods; for example, some methods are less specific than others and others involve the use of standards that are assumed to assay at 100.0%. Accuracy can be estimated to some extent in the case of formulations: known amounts of impurities can be added to a placebo and the percentage of each impurity recovered determined.

The detection limit is the smallest amount of analyte that can be detected but not necessarily quantitated as an exact value in a sample. For instrumental methods, the investigator may compare test results from blanks and samples of increasingly low concentrations and establish at which concentration the analyte signal is distinguishable above the noise. Usually a signal-to-noise ratio of 2:1 or 3:1 is acceptable.

The quantitation limit is the lowest amount of analyte in a sample that can be measured with a suitable degree of precision or accuracy. Several approaches for determining it are acceptable. Many investigators determine the concentration of analyte where the signal-to-noise ratio is 10:1; others may define it as the concentration at which the relative standard deviation (RSD) on a specified number of replicates is of a certain magnitude, for example, 10% for 5 replicates.

Precision expresses the degree of agreement between individual test results on the same sample. To determine the precision, a number of weighings of a particular sample are analyzed and the mean, standard

deviation, and RSD of the results are determined. Repeatability or intra-assay precision expresses the precision under the same operating conditions over a short interval of time. This is done by determining the mean response and RSD of replicate injections of a standard solution to obtain an estimate of the error that is attributable to the operating system only, excluding sample preparation. Generally, lower precision is required for related substances methods than for assay methods. Intermediate precision expresses within-laboratory variations such as different days, different analysts, different equipment.

The robustness of a method is a measure of its capacity to remain unaffected by small but deliberate variations in method parameters and provides an indication of its reliability during normal usage. It can be demonstrated by showing that operational or environmental influences have no significant effect on test results.

Ruggedness is the ability of the method to produce similar results for a given sample when it is used in a variety of normal test conditions, such as different equipment, different analysts, different laboratories, or different days. Having the method evaluated by another analyst, preferably in another laboratory, provides a means to evaluate the ruggedness of the method. Such an external evaluation may reveal that the instructions are ambiguous or incomplete, or that differences in results can arise due to the use of different brands of equipment or chemicals. Collaborative studies, such as those organized by AOAC International, in which a given set of samples is analyzed by a number of laboratories, are probably the best way of demonstrating the ruggedness and reproducibility of a method, but are seldom done for drug standard methods.

Linearity is the ability of the method to provide a measurable response to the analyte that is directly, or by a well-defined mathematical transformation, proportional to its concentration over a given range. It is usually determined from regression analysis of a plot of response versus concentration. The variance of the slope of the regression line, calculated by the method of least squares, provides a measure of linearity. Linearity is usually defined over a given range, e.g., for a related substances method, it is usually necessary to demonstrate linearity from the minimum quantifiable amount to an amount exceeding the proposed limit on individual impurities.

Sensitivity, though not defined in the ICH Validation Guideline, is a useful parameter to evaluate during method validation. It is defined as the slope of the analytical response curve. It is the difference in response for a given difference in concentration. When several compounds are quantified against a

single standard, it is necessary to show whether the system is more or less sensitive to these compounds, relative to the standard.

In order to develop monographs for new drugs the EP, USP, and JP require validation data and analytical results for production batches of drug substance or drug product that are consistent with ICH guidelines. The EP has adopted a policy of transparency with respect to validation data; this means that key aspects of the validation may be published or made available upon request. Key data may include the brands of column packing materials that have been evaluated or the names of the related compounds for which the method has been validated. Such a policy allows users to better understand the scope and limitations of particular methods.

### Techniques

Analytical techniques are based on a particular chemical or physical property. For example, spectrophotometry may be used for compounds with a UV chromophore or it may be possible to devise a titrimetric method based on the acid-base properties of the analyte. The solubility and stability of the drug and impurities in various media and under various conditions may also play a role in the choice of technique.

In 1990, chromatographic methods accounted for ~95% of the tests used to assess purity in USP monographs. Spectrophotometric methods accounted for less than 4% of methods. The remaining 1% included titrimetric, nuclear magnetic resonance, colorimetric, and other methods.

Spectroscopic methods include both UV and infrared (IR) methods. Both the BP and USP contain a UV method for adrenalone in adrenaline (epinephrine). Other drugs that are produced from the reduction of aromatic ketones or undergo oxidation to aromatic ketones have analogous tests; these include isoprenaline (isoproterenol) and metaproterenol (orciprenaline).

IR spectroscopy has been applied to determining the presence of an excess of one racemate in nadolol, defined as a 1:1 mixture of racemate A and racemate B. The USP test is based on the fact that a 1:1 mixture has a value of 0.9 for the ratio of the absorbance at  $7.9\ \mu\text{m}$  ( $1265\ \text{cm}^{-1}$ ), corresponding to racemate A, over that at  $8.00\ \mu\text{m}$  ( $1250\ \text{cm}^{-1}$ ), corresponding to racemate B. The USP limit for racemate composition is 40–60% racemate A. **Figure 1** shows the partial IR spectra of two nadolol samples from the same manufacturer. Samples B1 and B2 contained ~30% and 48% racemate A, respectively.

Melting point determination is a test that is included in most pharmacopoeias. Other thermal

**Figure 1** Infrared absorbance spectra obtained for the evaluation of racemate composition of two samples of nadolol from the same manufacturer. Sample NAD-B1 contained 30% racemate A; sample NAD-B2, 48% (USP limits 40–60% racemate A).

analysis methods such as differential scanning calorimetry and thermogravimetric analysis, although useful for purity determination and polymorphism studies, are not used on a routine basis.

Polarimetry can be used to monitor the presence of an unwanted enantiomer in some drugs. However, the determination of optical rotation is not a very specific test; in addition to the unwanted enantiomer, other chiral drug related impurities can affect the results.

As indicated above, chromatography is almost invariably used for impurity determination. Thus, many pharmacopoeial methods employ TLC to resolve the impurities from the drug with subsequent detection under visible or UV irradiation, or reaction to produce colored spots. Tests are based on a comparison of the intensity of impurity spots with that produced by a drug standard at a concentration corresponding to the limit for individual impurities specified in the monograph. A densitometric evaluation of the chromatogram may provide a more quantitative result than visual inspection. In some cases, impurity spots are scraped from the plate, extracted and quantified using a spectrophotometer. The main advantages of TLC are its simplicity, low cost, high resolving power, and relatively short analysis times.

LC provides good reproducibility and high-quality results; the cost is reasonable for routine applications and it is fairly easy to operate the equipment. UV-visible detectors are most commonly used for routine impurity determinations by LC. Other detectors that are useful for the identification of impurities or for specialized purposes are refractive index, fluorescence, electrothermal detectors, polarimeters, Fourier transform infrared spectrometers, and mass spectrometers.

The resolving power and sensitivity of LC are often greater than TLC. However, quantification is not possible unless the compounds are eluted from the column whereas in TLC all the components are on the plate and can be measured, if they are resolved, even if they do not move from the origin.

Figure 2 shows two samples of verapamil hydrochloride, VER-B1 and VER-D, analyzed using an LC method for chromatographic purity. This example illustrates a difference in impurity profile for lots originating from different manufacturers. Each sample contained less than 0.5% impurities.

GC is sometimes used for drug-related compounds and is the technique of choice for the determination of residual organic solvents in drug raw materials. Packed GC columns and wide-bore wall-coated open tubular columns are used in pharmacopoeial methods. Thermal

conductivity, flame ionization, and electron capture are the types of detectors most commonly used.

For residual organic solvents, the USP sets limits of 380  $\mu\text{g per g}$  for 1,4-dioxane, 600  $\mu\text{g per g}$  for methylene chloride, 80  $\mu\text{g per g}$  for trichloroethylene, and 60  $\mu\text{g per g}$  for chloroform. When warranted, some monographs contain an additional test for ethylene oxide for which the limit is 10  $\mu\text{g per g}$ . Several methods are described in USP general chapter (no. 467, *Organic Volatile Impurities*) and the one to be used for a particular drug substance is specified in the individual monograph. These methods are based on direct injection or dynamic headspace techniques.

LC has several advantages over GC: separations are usually carried out at ambient temperature and therefore thermal degradation is less likely to occur, derivatization is not normally required, and sample preparation is usually simpler, even for formulations. There are, however, some disadvantages when compared to GC: the resolving power of LC is generally lower, particularly when compared to capillary GC; and there is the problem of solvent waste disposal.

## Emerging Techniques in Drug Purity Determination

An increase in the variety of commercially available GC and LC columns has spawned an interest in developing methods to directly quantify optical isomers present as impurities in chiral drugs. These methods are viewed as generally more specific than tests for specific rotation and may soon be replacing such tests in pharmacopoeias.

Biotechnologically derived pharmaceuticals such as proteins from recombinant DNA (r-DNA) techniques or monoclonal antibodies pose new challenges. The absence of DNA at the picogram per dose level in r-DNA derived proteins must be demonstrated because such DNA could be incorporated into the human genome and become a potential oncogene. Host cell or host cell components (e.g., proteins, viruses) and substances used during production or purification (e.g., media, antibiotics, and reagents) are examples of potential impurities in these products. In addition, the organisms used during production must be monitored for mutations, which could result in new undesirable impurities. Well-established pharmacopoeial procedures suitable for detecting impurities in biotechnologically derived products include LC, the limulus amoebocyte lysate test for bacterial endotoxins, the rabbit pyrogen test, and gel electrophoresis. Newer techniques include peptide mapping, isoelectric focusing, capillary gel electrophoresis, and immunoassays.

**Figure 2** Chromatograms for two lots of verapamil hydrochloride analyzed by LC. Column:  $150 \times 4.6$  mm i.d.  $3 \mu\text{m}$  Spherisorb ODS-2; mobile phase: acetonitrile,  $0.01 \text{ mol l}^{-1}$  sodium acetate containing  $33 \text{ ml l}^{-1}$  glacial acetic acid, 2-aminoheptane (45:55:0.5 v/v/v); flow rate  $0.9 \text{ ml min}^{-1}$ ; UV detector 278 nm.

## Stability Testing

**T Coomber**, Pharmaceutical Development Consultant, Gravesend, UK

© 2005, Elsevier Ltd. All Rights Reserved.

## Introduction

A key component in a pharmaceutical development program for a new drug or formulation is the stability testing of the drug substance often termed active pharmaceutical ingredient (API) and the dosage forms used throughout the development of the marketed product or products. Stability tests have to be carried out so that recommended storage conditions and shelf life can be included on the label to ensure that the medicine is safe and effective throughout its shelf life.

The detailed analytical science behind many of the tools used in this activity is covered in various sections of this volume. No attempt has been made to go into the details of the methods for the identification of impurities or quantitative analysis of the main component and impurities. The exciting aspect for many involved with this process is to bring the various scientific threads together in the practical

determination of the storage characteristics of drugs and their formulations, the process of doing this in the limited time frame of the development of a new product, and the challenge of providing and influencing the regulatory information that has to be submitted.

Understanding the science behind the degradation of the drug substance in the solid state and more practically in solution enables a suite of tests to be chosen to monitor the crucial stability characteristics of the drug substance and gives a guide to the testing that should be carried out on the dosage forms.

In order to underwrite a shelf life, the stability of the dosage form should be understood in terms of appearance, degradation, and physical stability. Changes in appearance give rise to an instant query from the patient: ‘the medicine has changed, is this alright?’ Increased levels of impurities due to degradation have to be strictly controlled because of possible toxicity effects. Degradation also leads to a loss of active ingredients that will decrease the effectiveness of the treatment. The impact of physical change needs to be understood. For instance, moisture loss from a solution through a semipermeable container could lead to overdosing of the drug.

## Stability Testing

**T Coomber**, Pharmaceutical Development Consultant, Gravesend, UK

© 2005, Elsevier Ltd. All Rights Reserved.

## Introduction

A key component in a pharmaceutical development program for a new drug or formulation is the stability testing of the drug substance often termed active pharmaceutical ingredient (API) and the dosage forms used throughout the development of the marketed product or products. Stability tests have to be carried out so that recommended storage conditions and shelf life can be included on the label to ensure that the medicine is safe and effective throughout its shelf life.

The detailed analytical science behind many of the tools used in this activity is covered in various sections of this volume. No attempt has been made to go into the details of the methods for the identification of impurities or quantitative analysis of the main component and impurities. The exciting aspect for many involved with this process is to bring the various scientific threads together in the practical

determination of the storage characteristics of drugs and their formulations, the process of doing this in the limited time frame of the development of a new product, and the challenge of providing and influencing the regulatory information that has to be submitted.

Understanding the science behind the degradation of the drug substance in the solid state and more practically in solution enables a suite of tests to be chosen to monitor the crucial stability characteristics of the drug substance and gives a guide to the testing that should be carried out on the dosage forms.

In order to underwrite a shelf life, the stability of the dosage form should be understood in terms of appearance, degradation, and physical stability. Changes in appearance give rise to an instant query from the patient: ‘the medicine has changed, is this alright?’ Increased levels of impurities due to degradation have to be strictly controlled because of possible toxicity effects. Degradation also leads to a loss of active ingredients that will decrease the effectiveness of the treatment. The impact of physical change needs to be understood. For instance, moisture loss from a solution through a semipermeable container could lead to overdosing of the drug.

The 'in use' stability of the drug product is also tested. This is highly dependent on the product, but once the seal has been broken on a tablet container or a freeze-dried powder has been reconstituted then the stability of each under the less controllable conditions of a patient's home or a clinical setting should be established over the recommended period of dosing.

This scientific activity is controlled by government regulations that define the amount and scope of testing and the quality of the data that has to be provided in all major markets of the world. There are also guidelines on testing that have been produced by an umbrella organization called 'The International Committee for Harmonisation (ICH) of Technical Requirements for Registration of Pharmaceuticals for Human Use' and agreed between the authorities in Europe, Japan, and the United States and the manufacturer's organizations in those areas. Input from the World Health Organization (WHO) has also been included. These guidelines are now well accepted as an appropriate level of testing worldwide.

This testing is carried out as part of the development process of a new drug product. So the work has to be managed in the overall timescale and process of development and final data package must meet requirements on data quality and content.

## Drug Substance

For any new drug, the potential and, if possible, actual degradation processes need to be understood in order to develop appropriate analytical methods. Perversely, from a technical viewpoint, it is more straightforward if the drug degrades to a small extent. The mechanism also needs to be understood in order to develop a product with optimum stability (this may be a compromise between shelf life and storage conditions). The identification of degradation products and the monitoring of their formation and the level of the drug substance are, therefore, key components of the program. For drugs having isomeric forms, the likelihood of those forms interconverting needs to be understood as the activity and the toxicity of the forms may be different and they are viewed as different substances.

The understanding of the physical nature of the drug substance in terms of crystal form can also be crucial. This understanding will enable changes in moisture content to be avoided to enable accurate measurements of the drug substance throughout its use and to avoid having to take onerous packaging precautions. Similarly, especially for poorly soluble drugs, the most stable crystal form should be chosen as efficacy may change if the crystal form changes.

The potential for degradation should be considered in terms of the effect of heat, light, and oxidation in the solid state and also in the presence of acids and bases in solution or suspension. In preliminary studies, the drug substance will be stressed, usually at temperatures of 50–80°C in the solid and solution, at extremes of pH (about 1 and 13), and in the presence or absence of oxygen.

Solid-state degradation is not straightforward to model and predict as the first step is some sort of disruption of the crystal that has large activation energy. When this is true, although high-temperature studies may show degradation, the rate will decrease rapidly with decreased temperature, perhaps ~10-fold per 10°C decrease in temperature.

In solution the rate of degradation will often follow regular kinetics. It has been found useful to describe the rate of degradation as the time to 90% drug remaining,  $t_{90\%}$ , rather than use rate constants. Activation energies ranging from 50 to 100 kJ mol<sup>-1</sup> have been reported. With activation energies of this order,  $t_{90\%}$  will increase by a factor of ~2–3.5 for every 10°C rise in temperature. If the reaction undergoes specific acid or base catalysis in solution, the rate will change by a factor of 10 for every pH unit change in the appropriate pH region. This emphasizes the potential importance of adequate pH control. Under the controlled conditions of formulation, the degradation of the major product will often follow first-order degradation kinetics, which means  $t_{90\%}$  will stay constant over a range of concentrations of the drug.

In contrast, photolysis is a zero-order process and the  $t_{90\%}$  of a weaker solution will decrease in proportion to concentration.

Oxidation reactions will be controlled by the amount of oxygen present. A genuine oxidation of the drug is a major problem, but often oxidation reactions that effect formulations are of a secondary nature, i.e., often in conjunction with photolysis or catalyzed by the presence of trace metals so that degradation can be controlled by addressing those factors.

The limits on manufacture and shelf life for degradation products will be set by the knowledge of the amount present in the drug substance used in toxicity testing, by knowledge of the material itself, or by knowledge of compounds of a similar structure. (This is called qualification.) In the absence of such information, ICH sets pragmatic lower limits for unqualified degradation impurities in drug substance and drug product.

Several batches of the drug will be stored under the defined conditions to establish storage conditions and a retest date or shelf life.

## Dosage Form

Prior to dosage form, development compatibility studies with proposed excipients are carried out. This is an extension of the testing carried out on the initial investigation of the drug substance and should build on and expand the knowledge generated. For solid products, these studies are often carried out under high humidity with simple mixtures. A storage condition of 40°C and 75% relative humidity is often used. Solution products are tested at 50–70°C in a narrow range of pH compatible with the drug and the patient.

Some considerations on the testing of individual formulations are given below. However, the following tests are common to all formulations: appearance, strength (usually expressed as percent labeled strength), and related (degradation) impurities. A selection of other tests that are used is given in **Table 1**. Each formulation needs to be considered on its merits and there is also significant detailed advice from the regulatory bodies that should be followed.

### Tablets

Tablets are a mixture of the drug substance and excipients that enable a homogeneous mixture of the drug to be made and then a solid tablet to be compressed from that mixture. Tablets are often film coated to mask taste and/or to give a consistent appearance. Water is often present in the excipients and can be used as part of the manufacturing process in wet granulation, often providing a medium for potential degradation on manufacture and storage.

To obtain a precise assay, the ratio of the drug substance to excipients in the tablets needs to be considered when deciding on the number of tablets taken. There are pharmacopeial standards for content and/or weight uniformity of the tablet, and the variability of the batch will be established using this

test. In general, a sample of 5–10 tablets needs to be taken to obtain sufficient accuracy. The sample preparation is best achieved by using whole tablets. It is rare for the excipients to dissolve completely, so physical disruption of the tablets in an ultrasonic bath or with a high sheer mixer is often employed. A filtration or centrifugation step may be required, although it is not always necessary if subsequent dilutions are made. Changes in the tablet on storage (e.g., increased hardness) can lead to difficulties in sample preparation. As high-performance liquid chromatography (HPLC) analysis is often the final step, the final diluent should be chosen to minimize any affect on the chromatography.

Tablets will normally have a dissolution test and this should remain within specification throughout the shelf life of the product. This is particularly important for compounds that are poorly absorbed and of low solubility, where changes in dissolution characteristics may indicate potential delivery problems.

### Capsules

A capsule is made from either a hard or soft shell using gelatin or other materials that will dissolve rapidly in the stomach. Hard capsules are usually filled with a mixture of the drug substance and an inert bulking agent such as lactose. Soft capsules are filled with an oily solution or suspension. Sample preparation can either be by opening the capsules and transferring the contents or by using gentle warming in an aqueous medium to dissolve the shell. The impact of moisture on the contents should be considered as the shell will transmit water. Hardening of the shell can also occur on storage, which can effect the sample preparation.

### Liquids

Liquid formulations will have defined pH, and testing will be carried out on formulations manufactured

**Table 1** Summary of other tests by product

<i>Product</i>	<i>Test requirements</i>
Tablets	Color, odor, dissolution (disintegration), moisture, friability
Capsules	Color, odor of contents, dissolution, moisture, microbial limits
Emulsions	pH, color, odor, viscosity, microbial limits, preservative content, dispersed phase sizing
Oral solutions and suspensions	pH, color, odor, preservative content, microbial limits, suspension characteristics
Metered dose inhalers	Delivered dose, number of doses, particle size distribution
Topical ophthalmic and otic preparations	pH, color, odor, homogeneity, preservative content, antioxidant content
Parenterals	pH, color, particulate matter sterility and pyrogenicity, preservative content, other tests as in type of formulation

This list is indicative of the types of test and is not complete. The appropriate regulations should be consulted and applied to the particular formulation and justified by the science.

at the target pH and at the expected limits. They will also, in general, include preservatives to prevent microbial contamination. The stability of these preservatives will need to be monitored and they will often be determined by HPLC simultaneously with the drug content. It will need to be confirmed that the product is adequately preserved at the end of the shelf life.

### Oral Solutions and Suspensions

These may contain levels of sugars or artificial sweeteners, coloring and flavoring agents, which make the HPLC determination more complex. Many of these components will be detected by HPLC and may interfere with the components that are being determined. The container should be stored such that the contents are in contact with the closure system.

### Parenterals (Injections)

These include solutions, suspensions, and powders for reconstitution and are often produced as sterile single-dose or preserved multiple-dose products. In terms of testing the general considerations for liquids apply. Particle size monitoring of suspensions should be carried out. Interactions with any closure system should be tested. Attention also has to be paid to sterility testing during the stability study.

### Topical Creams and Ointments

These cover a wide range of formulation types from ointments to nonmetered aerosols. The physical status of an emulsion can be critical. This is tested by temperature cycling. Where appropriate the homogeneity of the content is also monitored by sampling the top, middle, and bottom of the container.

### Metered Dose Inhalers

As well as the chemical testing, inhalers require specific characteristics to be determined. Dose delivery and number of doses and particle size, which is crucial for delivery to the lung, should be determined. The testing for inhalers is a labor-intensive activity. The robustness of the delivery, number of doses and particle size, system, the container and valve seal, and propellant losses are all determined.

## Analytical Considerations

The common tests for stability testing are appearance, strength (content), and degradation impurities. In order to monitor stability, a quantitative test is best as it will demonstrate a trend. Thus, a description of color, for instance, may be best made by an instrumental approach. Pharmacopeial requirements

for quantitative tests such as HPLC should be followed.

For the determination of strength and degradation, the primary tool for the analytical chemist involved in stability testing is HPLC with ultraviolet (UV) detection.

In the early stages of development, this is used firstly as a separation tool to establish what degradation products are produced. In conjunction with a mass detector, this will often enable the identity of the impurity to be proposed. Confirmation of structure is often achieved by the use of nuclear magnetic resonance spectroscopy and mass spectroscopy or by synthesis.

In routine storage tests, HPLC will also be used to monitor the formation of degradation impurities in both the drug substance and the formulated product, and generally to determine the amount of the active material present. HPLC is not the only tool that can be used. Capillary electrophoresis has great separating power and is often useful in separating optical isomers. The choice of method is a question of understanding the scientific and practical scope of the different tools that are available. UV spectroscopy can be used to measure the active material in a product in dissolution and homogeneity studies, for instance.

A method of analysis for degradation (and synthetic) impurities may need to have a limit of quantitation of  $\sim 0.03\%$  as this is the lowest reporting threshold required. The lowest limit for unqualified impurities can be  $0.05\%$ . In the analysis of products, the limit for unqualified impurities ranges from  $0.05$  to  $1.0\%$  depending on the dose. During routine testing, a combination of a suitability test using a mixture of the drug substance and a critical (from a separation standpoint) impurity and relative retention time will be used to identify a degradation product. Usually, this determination will be carried out using the drug substance as a quantitative reference material and an experimentally measured response factor. Responses between  $0.8$  and  $1.2$  can be assumed to be  $1.0$  for practical purposes. These determinations are well within the scope of current automated HPLC with an integration system.

In drug product analysis, the amount of the drug substance remaining is commonly determined simultaneously with that of impurities using an external standard of a drug substance reference compound produced as part of the development process for new drugs or from a Pharmacopoeia, when available, for established drug substances. Using automated injection and data handling systems, an accurate and precise assay can be achieved. Simultaneous determinations of active impurities provide the challenge

of quantification over a large dynamic range, but this is within the scope of the art and should be carefully considered during method development.

The most critical stage of any study will be the appearance of the primary degradation product and this will usually be in excess of the limit well before there is a detectable change in the main component assay. The assay is, however, important to ensure there is mass balance (i.e., we are not losing drug through an unexpected degradation) and to demonstrate that there have been other changes in the formulation (i.e., loss of water or other solvent through a semipermeable container leading to an excess dose being delivered) or loss of the active component to the walls of a container.

## Process and Timing

The development of a new drug runs through a series of four phases. The determination of stability characteristics is an ongoing activity during that process.

Phase I is taken to cover the development of the drug from the proof of concept (i.e., some information in a disease model that the compound is active and worth the investment in developing) through acute toxicity studies until it is dosed to human volunteers. Stability data are generated to ensure the model has actually been challenged by the drug and not a degradation product. The requirements of good laboratory practice (GLP) require that the formulation used in animal studies is adequately stable for the duration of use of the formulation. Similarly, the stability of the formulation used in the Phase I clinical studies needs to be underwritten. This assurance will be required by the investigators, the ethics committee of the organization carrying out the study, and in some countries the regulatory body of the country concerned.

Phase II studies are those carried out in the patient population to establish whether the drug is active in the patient and also establish the optimum dose. Longer-term toxicity testing will also be carried out. As before, GLP will require the formulations used for toxicity testing to have their stability assessed. The clinical formulations will also have to be tested and will usually be made under the control of good manufacturing practice (GMP) regulations. These data are required to be generated to a protocol that covers the expected shelf life of the formulations. The regulatory bodies will require protocols and/or data summaries and an ongoing commitment to testing. The conclusion from 3 months data is a common minimum requirement in a submission for approval to carry out a clinical trial.

Phase III studies are those carried out on the formulation proposed for marketing. This is where the

testing requirements expand in terms of batches tested and amount of data and where the ICH requirements operate. One year data on three batches of defined sizes in comparison to production scale are required for submission in the dossier for approval for marketing in the EEC (Marketing Authorization Application, MAA) or in the USA (New Drug Application, NDA).

Phase IV studies are those carried out after the drug is first released and will include additional formulations that have to meet the same requirements as phase III. There is also an ongoing commitment to complete the studies commenced in phase III until the end of shelf life, and a requirement for ongoing testing of a subset of production batches of all marketed formulations under GMP regulations.

## Regulation and Guidelines

The stability testing of pharmaceuticals is regulated by national and international agencies. Four major bodies, the Food and Drug Administration (FDA) (through the Centre for Drug Evaluation Research, CDER), the European Agency for the Evaluation of Medicinal Products (EMA) (via the Committee for Proprietary Medicinal Products (CPMP)), Ministry of Health, Labor and Welfare (MHLW), Japan, and the WHO, publish requirements on the storage conditions, testing times, and amount of data needed to establish the shelf life required for drug products to be licensed for use. For new products, these stability testing requirements have been the subject to over 10 years of worldwide harmonization through the ICH process and are now available from individual registration bodies and from the ICH. In particular, the storage temperature and humidity conditions required to cover storage in normal climatic conditions have been defined for four different climate areas covering most of the world's population.

The data, testing requirements, and standards are laid out by each body and include extra guidance in addition to that provided by the ICH for new products and guidance on existing products that are not formally covered by the ICH process.

Laboratory standards required are also controlled by quality programs. In particular, the stability testing of materials for safety testing in animals is controlled by the GLP regulations. The testing of materials for registration of final products is performed under the GMP regulations that apply to materials made in full-scale production.

ICH stability testing guidelines are available on the Internet, see **Table 2**, and there is a process by which they are introduced eventually into official status in the USA, EEC, and Japan.

**Table 2** ICH guidelines on stability testing

Number	Title
Q1A(R2)	Stability Testing of New Drugs and Products (Revised Guideline)
Q1B	Photostability Testing
Q1C	Stability Testing for New Dosage Forms
Q1D	Bracketing and Matrixing Designs for Stability Testing of Drug Substances and Drug Products
Q1E	Evaluation for Stability Data
Q1F	Stability Data Package for Registration Applications in Climatic Zones III and IV
Q2A	Text on Validations of Analytical Procedures
Q2B	Methodology
Q3A(R)	Impurities in New Drug Substances (Revised Guideline)
Q3B(R)	Impurities in New Drug Products (Revised Guideline)
Q5C	Stability of Products (Biotechnology Products)

Q1A gives recommendations on the stability testing protocols that should be followed to assess the stability of new drug substances and products. Recommendations are given on temperature and humidity levels as well as the duration of trials. Q1B forms an annex to the main stability guideline, and gives guidance on the basic testing protocol required to evaluate the light sensitivity and stability of new drugs and products. Q1C extends the main stability guideline and defines the circumstances under which reduced stability data can be accepted, at the time of filing an application, in the case of new formulations of already approved medicines. Q1D gives guidance on specific experimental designs to optimize the amount of testing. Q1E amplifies the guidance on extrapolating data for shelf life determinations, and Q1F amplifies the requirements for the more extreme climate zones.

All analytical methods used should be validated appropriately as laid out by the regulatory bodies and ICH guidelines available in Q2. The guidelines on impurities in Q3 are also relevant to setting the limits for degradation impurities. The Q5 guidelines give information on the testing of biotechnology products.

There are additional guidelines from the CPMP in Europe (see Table 3).

The FDA has also issued Draft Guidance on stability testing of drug substances and drug products, which includes and extends the scope of the ICH Guidelines and includes guidance on phases I and II and testing for postapproval changes.

These documents are called guidelines although they eventually have legal status in the USA. The principles behind them should be considered and applied where the guideline is not directly applicable

**Table 3** CPMP additional guidelines for stability testing

Number	Title
CPMP/QWP/609/96	Note for guidance on Declaration of Storage Conditions for Medicinal Products Particulars and Active Substances
CPMP/QWP/122/02	Note for guidance on Stability Testing of Existing Active Substances and Related Finished Products
CPMP/QWP/072/96	Note for guidance on Start of Shelf-Life of the Finished Dosage Form
CPMP/QWP/2934/99	Note for guidance for In-Use Stability Testing of Human Medicinal Products
CPMP/QWP/576/96	Note for guidance on Stability Testing for a Type II Variation to a Marketing Authorization
CPMP/QWP/556/96	Note for Guidance on Stability Testing of Existing Active Substances and Related Finished Products
CPMP/QWP/159/96	Note for guidance on Maximum Shelf-Life for Sterile Products after First Opening or following Reconstitution

and the reasons for a departure explained by a careful scientific rationale.

## The Future

The critical area of stability testing is the amount of data generated and the number of tests required. There will be a continued drive to reduce this where patient safety is not compromised.

The ICH process led to a commonality of requirements in the major markets. The ICH do have a proven mechanism to introduce change into guidelines and the FDA through their recent initiative, A Risk-Based Approach to Pharmaceutical GMP, are looking to embrace changes in testing procedures and approaches. However, the regulatory process is perceived as a barrier to change and industry tends to take a conservative approach to minimize the very expensive risk of the rejection of a data package.

In the early stages of development, there are opportunities to predict routes and rates of degradation. There are a number of published studies of degradation routes, so simple prediction for new molecules is possible and an intelligent database could be constructed to assist that process. A properly conducted scientific determination of the routes of degradation would still have to be carried out but this could be more focused and less time consuming. Advances in understanding the degradation behavior of the solid state for both pure substances and mixtures would be welcome.

The kinetics of reaction is a little more difficult to predict but the activation energy of many

degradation reactions in solution is in the order of 50–100 kJ mol<sup>-1</sup>. This implies that the  $t_{90\%}$  will change by a factor of 2–3.5-fold per 10°C change in temperature. Genuine solid-state reactions have far higher activation energy of up to 300 kJ mol<sup>-1</sup>, leaving the rate change of a factor of ~10-fold per 10°C change in temperature. So ball park predictions from a single accelerated temperature determination of rate are possible and an early risk assessment could be made.

The analytical science of stability testing includes the identification of degradation routes and the quantitative assessment of these in a highly regulated environment. Advances in the availability of the identification techniques especially with coupled HPLC determinations will continue to be made and utilized.

In the quantitative field, HPLC analysis and data handling are extensively automated. Sample preparation is often the rate-determining step. Automated sample preparation equipment is available and is of value for large sample numbers, but requires extensive validation studies. The analytical challenge of quantitative mixture determination is adequately met by automated HPLC. *In situ* analysis of whole tablets using near-IR chemometric approaches has been successfully demonstrated although this has not been applied to stability testing. It has also been demonstrated that low levels of an impurity can be determined in drug substances without separation using a chemometric approach. The regulatory environment has been skeptical of the use of chemometrics and the practical technology would require investment in time and development for a marginal short-term return although undoubted long-term rewards. Although the determination of content should be carried out by a stability indicating method, the product will generally go out of specification from the degradation impurities increasing before the assay shows a significant change. There is potential,

therefore, to use faster and less specific methods for the assay when this can be justified scientifically.

The use of experimental design to reduce the amount of testing has been accepted and is enshrined in the ICH guideline on bracketing and matrixing, so there is certainly some scope to further explore the options in this area.

It is expected that the rate of change of approaches will be slow and likely to be incrementally based on current technology.

## Dissolution Testing

**S Bateman**, Longfield, UK

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

Dissolution testing is a means of monitoring the rate of release of a drug substance from an oral pharmaceutical dosage form, and is widely used within the

pharmaceutical industry during formulation development, for quality control, stability testing, the prediction of bioavailability, and to assist in the determination of bioequivalence.

In early drug development, dissolution testing may yield important information when comparing different formulations. For some drugs, dissolution rate may provide a useful indication of the bioavailability of a preparation, provided a correlation between

*in vitro* dissolution and *in vivo* bioavailability has been established. For example, successful *in vitro/in vivo* (IV/IV) correlation has been established for digoxin tablets containing different particle sizes of the drug substance.

For quality control purposes, dissolution testing is a means of ensuring batch-to-batch consistency and compliance with specifications. Dissolution rate may be able to highlight whether any serious changes or faults have occurred in the formulation, manufacture, or storage of a product.

Increased interest by regulatory authorities has emphasized the importance of dissolution testing, and has led to significant modifications and improvements in equipment. Comparison of dissolution profiles is being widely used in assessing product uniformity, particularly in the regulation of postapproval changes to formulation, site of manufacture, scale of manufacture, and/or the manufacturing process and equipment.

## Apparatus

A comparison of compendial dissolution techniques is given in Table 1.

### Paddle and Basket Apparatus

The United States Pharmacopeia/European Pharmacopoeia/Japanese Pharmacopoeia (USP/EP/JP) rotating paddle apparatus (Figure 1) is recommended for

the vast majority of oral dosage forms. It is the simplest system to operate and fully automated equipment is available from a number of manufacturers. The dosage form is placed directly in the dissolution medium (maintained at 37°C) and the paddle is rotated. Samples of the fluid are removed at predetermined intervals, filtered immediately to remove undissolved drug particles, and analyzed for drug content.

**Figure 1** Rotating paddle apparatus.

**Table 1** Compendial dissolution techniques

Apparatus	Compendial status	Agitation method	Advantages	Disadvantages	Application
Basket	USP 1 EP basket JP method 1 BP I	Rotating stirrer	Dosage form confined leads to consistent solid/liquid interface Floating products kept immersed	Limited sink conditions Trapped bubbles in basket can slow dissolution rate Inadequate mixing at slow speed	Floating dosage forms Dosage forms that tend to adhere to the vessel surfaces
Paddle	USP 2 EP paddle JP method 2 BP II	Rotating stirrer	Simple to use and automate Widely available	Limited sink conditions Sinkers needed for floating dosage forms Coning <sup>a</sup> can occur with large dosage forms	Majority of solid dosage forms Suspensions
Reciprocating cylinder	USP 3	Reciprocating	pH changes are easy Easy to automate	Carryover and incomplete drainage between rows Usually only applicable to nondisintegrating dosage forms	Delayed/extended release products Bead products
Flow-through	USP 4 EP flow-through JP method 3 BP III	Continuous flow	Sink conditions maintained for low solubility drugs pH changes are easy	Large volumes of dissolution medium required Tendency of filters to clog Thorough deaeration of medium necessary	Low solubility drug products Extended release products

<sup>a</sup> The accumulation of material at the bottom of the vessel.

**Figure 2** Rotating basket apparatus.

For some products the USP/EP/JP rotating basket apparatus (Figure 2) may be more appropriate; for example, in the case of floating capsules and granules. Operation of the basket apparatus is similar to that of the paddle apparatus, except that the basket containing the dosage form is immersed in the dissolution medium prior to starting the rotation.

Rotation speeds of 50 or 75 rpm for the paddle apparatus and 50 or 100 rpm for the basket apparatus are recommended for tablets, pellets, and capsules. The paddle apparatus at 25 rpm is recommended for suspensions. In general, mild rather than vigorous agitation conditions will allow for greater discriminating power to detect potentially significant changes in dosage form performance.

The volume of dissolution medium is generally within the range 500–1000 ml, and for most applications the pharmacopoeial norm of 900 ml is used.

### Flow-Through Apparatus

The USP/EP/JP flow-through apparatus (Figure 3) should be considered if the drug substance exhibits low solubility or if pH changes to the dissolution medium are required during the dissolution test, as in the case of controlled or delayed release products.

The dosage form is placed in a cell on a bed of glass beads or on a wire tablet holder. The pump forces the dissolution medium upwards through the cell. Filters prevent undissolved particles from escaping from the top of the cell. Analysis of the eluate may be performed directly online or by the collection of fractions at each specified time point.

**Figure 3** Reciprocating cylinder apparatus.

Typical flow rates are 4, 8, 16, and 32 ml min<sup>-1</sup> and standard cell diameters are 12 and 22.6 mm. For most formulations a flow rate of 16 ml min<sup>-1</sup> using the 22.6 mm cell are appropriate.

The bed of glass beads normally used to ensure laminar flow within the cell may be omitted (combined with a low flow rate) when investigating IV/IV relationships to more accurately reproduce conditions found within the small intestine.

### Reciprocating Cylinder

The reciprocating cylinder (USP apparatus 3) (Figure 4) is useful for nondisintegrating extended-release products, particularly where accurate IV/IV correlation is needed.

**Figure 4** Flow-through apparatus.

The apparatus consists of a set of transparent cylinders, capped at each end with a screen, in which the dosage form is enclosed. The cylinders are gently moved up and down (the dip rate) in dissolution medium contained in glass tubes held in a water bath. The medium enters the cylinders allowing dissolution to occur. At the specified times the reciprocating cylinders are raised and a portion of the solution is removed for analysis.

### Other Apparatus

The USP also lists three other dissolution apparatus for transdermal delivery systems, apparatus 5 (paddle over disk), apparatus 6 (cylinder), and apparatus 7 (reciprocating holder).

## Dissolution Media

The medium selected should be based on the physicochemical properties of the active ingredient(s) and the relevance of the medium to the performance of the dosage form in the body. This particularly applies to the pH and ionic strength of the medium.

In the case of drugs with high aqueous solubility in the range pH 1.2–6.8, the adoption of test conditions without regard to discriminating power (ability to distinguish between batches) is acceptable, provided dissolution rate does not affect bioavailability and is not influenced by formulation or manufacturing variables.

If it is known that the dissolution rate has a significant effect on bioavailability, or if formulation or manufacturing variables affect dissolution rate, then an attempt should be made to develop test conditions that can distinguish between these changes.

Generally, the objective is to select a medium in which sink conditions are maintained so that the drug already in solution does not exert a modifying effect on the dissolution of the remaining drug. For low solubility drugs it may not be possible to achieve sink conditions, and so it may be preferable to test formulations of these drugs under nonsink conditions that accurately reflect the *in vivo* situation.

The pH of the medium is usually within the range pH 1.2–8.0. Water, traditionally a first choice dissolution medium, is now considered less than ideal for most new dissolution tests. Reasons for this include lack of *in vivo* relevance and lack of buffering capacity.

Hydrochloric acid (0.01 or 0.1 mol l<sup>-1</sup>) is the preferred medium for drugs that are readily soluble at gastric pH. Aqueous buffer solutions are used when solubility, dissolution rate, or drug stability are pH dependant. The use of simulated gastrointestinal fluids (from the USP), with or without enzymes, may be justified in some circumstances.

Surfactant solutions are recommended for drugs that are poorly soluble in aqueous media but have increased solubility in surfactant solutions. The addition of low concentrations of surfactants such as polysorbate, sodium lauryl sulfate, and hexadecyltrimethylammonium bromide may allow sink conditions to be obtained, although foaming can be a problem.

A summary table for selecting the most suitable media for immediate release products is given in **Table 2**.

Delayed-release dosage forms (enteric coated) require a two-stage dissolution test, first in simulated gastric fluid to ensure drug is not released in the stomach, and then in simulated intestinal fluid to ensure drug release in the intestine.

**Table 2** Dissolution medium options

<i>Dissolution medium</i>	<i>Comments</i>
0.01 mol l <sup>-1</sup> Hydrochloric acid	First choice for a low pH medium, and now the recommended medium for gastric soluble drugs. Recent USP guidance suggests 0.01 mol l <sup>-1</sup> is more appropriate than traditionally used concentration of 0.1 mol l <sup>-1</sup>
0.1 mol l <sup>-1</sup> Hydrochloric acid	Recommended as the simulated gastric fluid for the first phase of testing for enteric-coated products. Widely used for existing products
Water	No longer a recommended medium for most new dissolution tests. Still widely used for existing products
Buffer solutions	Useful when solubility/dissolution rate is pH dependant or when chemical stability is pH dependant. Recommended buffered media are pH 1.2, 1.5 (HCl media), 4.5, 5.5, 5.8, 6.8, 7.2, and 7.5 (phosphate buffers)
Surfactant solutions	Recommended for poorly soluble drugs in combination with the paddle apparatus
Simulated gastro and intestinal fluids with enzymes	Recommended for aged gelatine capsules (may be used as the second method)
Physiologically based or biorelevant media	Useful for predicting food effects during formulation development of poorly soluble drugs and for IV/IV correlation. Suggested media are fasted state simulated intestinal fluid and fed state simulated intestinal fluid
Nonaqueous	Last resort for insoluble drugs. Not recommended

For extended-release dosage forms it is beneficial to establish an IV/IV correlation. Media that mimic the *in vivo* conditions are more likely to give reliable IV/IV correlation. If the majority of drug release is in the intestine, media in the pH range 6.8–7.5 should be considered. If the release of drug from the dosage form is pH, bile salt, or osmotic potential dependant, pH changes to the dissolution medium during the test may improve the chances of a reliable IV/IV correlation.

## Methods of Detection

Ultraviolet (UV)/visible spectrophotometry is the most widely used technique as it is simpler and easier to automate. High-performance liquid chromatography or other methods are usually only considered when it has been established that UV/visible spectrophotometry (including derivative UV and multi-component analysis) is not feasible or when the drug product contains more than one active ingredient.

If continuous monitoring of the dissolution medium is adopted through the use of flow-cells or fiber optics,

**Table 3** Typical dissolution data for instant and controlled release products

<i>Time (min)</i>	<i>% labeled strength dissolved (mean of 6)</i>		
	<i>Tablet formulation of a high solubility drug</i>	<i>Tablet formulation of a low solubility drug</i>	<i>Controlled release capsule formulation</i>
15	93	69	—
30	98	82	—
45	100	89	—
60	—	91	24
240	—	—	53
480	—	—	87

then the method is normally validated against manual sampling.

## Dissolution Limits and Interpretation of Results

Dissolution limits are established to ensure batch-to-batch consistency and to signal potential problems with bioavailability. The most widely used acceptance criteria are those of the USP but acceptance criteria are also given in the BP and JP (check against the current editions). IV/IV correlation may be used to establish these criteria if bioavailability data are available for batches showing different release rates.

Generally, the dissolution test is required to be performed on a total of six dosage units. A dissolution profile may be generated by sampling at 15 min intervals. For rapidly dissolving products, sampling at 5 or 10 min intervals may be necessary to produce an adequate profile. For immediate-release formulations a single time point limit is usually specified to ensure that most of the active ingredient is released within the preset time (typically 70–80% released after 15, 30, or 45 min). For extended-release dosage forms, limits are normally set at a minimum of three time points. The first limit is set to prevent dose dumping (rapid release if the drug) and should therefore correspond to ~20–30% released. The second limit should define the dissolution pattern and thus be set ~50% release. The final limit is specified to ensure almost complete release of drug, i.e., > 80%. Examples of various dissolution data are given in Table 3.

## Calibration of Dissolution Apparatus

To ensure reproducibility of dissolution data from one apparatus to another it is essential that the apparatus complies with the dimensions and tolerances

**Table 4** Parameters influencing calibration

Parameter	Comments
Location	Strong, level bench required
Vibration	Minimize vibration from external sources, e.g., heaters, pumps
Dimensional verification	Dimensions of equipment must comply with pharmacopoeias
Head plate co-planarity	Head plate (holding the shafts) must be level with the base plate (holding the vessels)
Shaft perpendicularity	Basket and paddle shafts must be perpendicular to the base plate
Centering vessels to the stirrer shaft	Distance between shaft axis and vertical axis of the vessel should be $\leq 2$ mm
Stirrer height	Distance of stirrer from bottom of vessel should be $25 \pm 2$ mm
Rotation speed	Speed of rotation of paddle or basket stirrer should be within $\pm 4\%$ of the specified value
Eccentricity (wobble or run out)	Each paddle or basket shaft must be straight along its entire length to ensure smooth stirring characteristics
Temperature of dissolution medium	Medium temperature should be controlled to $37 \pm 0.5^\circ\text{C}$
Flow rate (flow-through apparatus only)	Flow rate of dissolution medium through cells should be within $\pm 5\%$ of the set value

specified in the pharmacopoeias. There are a number of parameters that can lead to a calibration failure and these are summarized in **Table 4**, although it is possible for other factors to have an effect.

Reference tablets of known dissolution rate are available from the USP to determine apparatus suitability. Prednisone tablets (disintegrating) and salicylic acid tablets (nondisintegrating) may be used to check the calibration of the basket, paddle, and flow-through apparatuses. Chlorpheniramine extended-release tablets and theophylline extended-release beads have recently become available for checking the calibration of the reciprocating cylinder apparatus.

## Intrinsic Dissolution

During early formulation development it is useful to have a constant, defined surface area exposed to the dissolution medium in order to compare dissolution rates of drug substances. Typically, intrinsic dissolution is carried out using a compressed disk of material with only one side exposed to the dissolution fluid. Comparison of intrinsic dissolution rate may be especially useful when characterizing different salts,

polymorphs, or milling methods of the same drug substance.

## Sample Preparation

R Whelpton, University of London, London, UK

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

No matter how sophisticated the analytical equipment, the results will be rendered worthless if the sampling, sample storage, and sample preparation are not performed correctly. Thus, it is important to be familiar with the chemistry of the analyte and the nature of the sample matrix. Knowledge of the history of the sample is desirable; this entails knowing from where it originates and how it has been obtained, stored, and transported. Whenever possible, the analyst should be involved in the design of any protocols relating to drug dosing and sample collection. There is little point in assaying plasma samples that have been collected through an indwelling cannula that was used for administration of the drug (or samples collected from the same limb for that matter). The phlebotomist should be warned not to swab with alcohol if the sample is to be assayed for ethanol. It may sound fatuous, but such things occur; a problem during a study with chlorhexidine was traced to sampling with apparatus that had been sterilized with the compound being assayed.

### Sample Types and Storage

The range of samples submitted to analysis extends from pure solutions of a pharmaceutical ingredient to a putrefying piece of tissue for forensic analysis. Liquids, such as blood, plasma, serum, saliva, urine, and cerebrospinal fluid, are generally easier to sample than solids and semi-solids. However, they are not necessarily homogeneous with regard to drug concentration. Feces are not homogeneous, and determination of 24 h drug excretion rates will require that the entire sample be taken for analysis; something to remember when the experiment is being planned. Tissues need homogenization or digestion prior to sampling. With soft tissues, such as brain and liver, this can be done with a polytetrafluorethylene (PTFE)-in-glass homogenizer, but lung and muscle generally require something with a cutting or mincing action. Alternatively the tissue may be digested with a proteolytic enzyme – a technique frequently used in forensic and toxicological analyses. Enzymes can be used to ‘release’ plasma-bound drugs, but this may also release interfering substances.

### Blood and Blood Fractions

A decision should be taken as to whether whole blood, plasma, or serum is to be assayed. For drugs that are not distributed into erythrocytes, the concentration in plasma will be higher than that in blood, and there is little point in contending with red cells if plasma or serum can be used. Collection of plasma requires an anticoagulant, and an appropriate choice has to be made. Some drugs have been reported to bind to heparin, resulting in a loss of extraction efficiency. Plasma, as opposed to serum, may be chosen when it is thought that enzymic degradation of the drug requires  $\text{Ca}^{2+}$  or  $\text{Mg}^{2+}$ , the idea being that the chelating agents will bind these ions. The concentration of fluoride in fluoride oxalate tubes is unlikely to be sufficient to inhibit plasma esterases, which may not be inhibited completely by fluoride even at very high concentrations. The anticoagulant in citrate tubes is in aqueous solution, and the sample will be correspondingly diluted, a fact that has not always been recognized.

For some applications serum may be preferred to plasma. Problems with anticoagulants, including use of lithium heparin tubes for samples to be assayed for lithium and fibrinogen precipitation on freezing and thawing are avoided, but the delay while the clot forms and binding of analyte to the clot must be considered. Drugs may be metabolized differently in blood compared with in plasma. For example, at therapeutic concentrations pyridostigmine is lost rapidly from human blood but only slowly from plasma. Analyte stability in blood is rarely considered when the analysis is to be performed on plasma or serum but may be important, particularly if the plasma is not separated immediately after the blood has been taken.

For drugs that are extensively ‘bound’ to red cells, e.g., chlorthalidone concentrations can be 40 times higher in red cells than in plasma due to binding to carbonic anhydrase, an imperceptible degree of hemolysis will result in elevated plasma or serum concentrations. Addition of stabilizers to blood could affect the plasma:red cell distribution of a drug, as could temperature and pH (see later), and so for some drugs it may be better to assay whole blood. The problem of disruption of the cells on freezing and subsequent sampling of blood can be overcome by having known volumes of blood pipetted into extraction tubes while it is fresh.

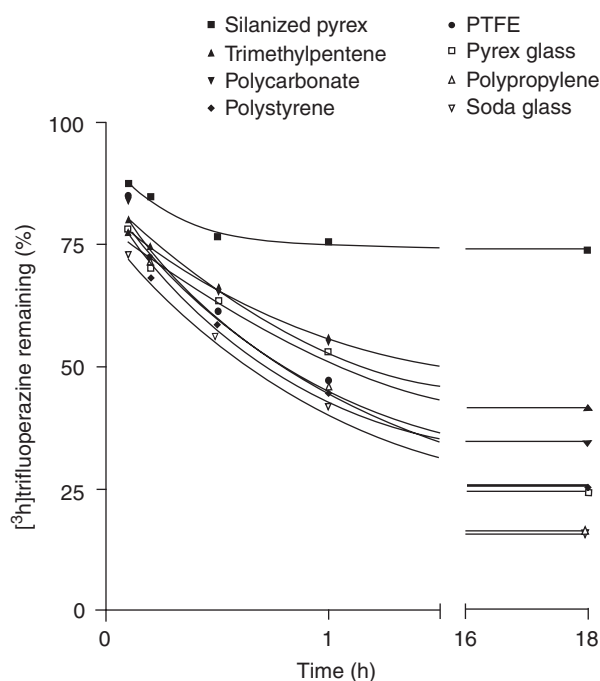

Having chosen the fluid to be assayed, the problem of preparing calibration standards should be

considered. Commercially obtained plasma (human and animal) frequently contains high concentrations of lignocaine (lidocaine) and may be diluted with citrate solution. The pH of stored plasma may have to be adjusted as it tends to be higher than physiological pH, presumably due to the loss of CO<sub>2</sub>. Blood for calibration standards is problematic; it cannot be frozen without disrupting the red cells, and when drug is added to fresh blood it may take several hours for equilibration between plasma and erythrocytes.

### Containers

The choice of containers, their labeling, transportation, and storage are no less important to the success of an assay than the choice of detection system or chromatographic conditions. Drugs may be lost from, or contaminated by, inappropriately chosen containers. For volatile compounds such as halothane, plastic containers and stoppers should not be used. Glass tubes with aluminum-lined screw caps are generally suitable for such analytes, but to reduce loss on sample transfer, the tube should be filled so as to avoid air spaces. Cooling samples to 4°C before transfer may help reduce losses. An alternative, if headspace analysis is to be used, is to sample directly into preweighed headspace vials. Loss of drugs onto glass and into plastics is well known, but it must be remembered that different types of glass and plastic behave differently, and what may be suitable for one analyte may not necessarily be suitable for another. PTFE-lined caps are preferred by some as being inert, but it is not necessarily 'nonstick' as far as drugs are concerned (Figure 1). Adsorption of basic drugs onto glass is sometimes reduced by addition of amine modifiers (triethylamine, ethanolamine, etc.), in the same way that they are used to reduce peak tailing on high-performance liquid chromatography (HPLC) columns, or high concentrations of a related drug may be introduced to compete for the binding sites. This approach was adopted in a gas chromatography electron-capture detection (GC-ECD) assay of chlorpromazine, high concentrations of promazine, which has weak electron-capturing properties, being added at high concentrations to compete for adsorptive sites on the extraction tubes.

Interferences from plastic containers are often plasticizers that leach into the sample. If they produce strong responses in the electron capture detector, then even small quantities can have a deleterious effect on an assay. Phosphate-based plasticizers have caused problems with nitrogen-phosphorous detection. Furthermore, it has been shown that tris (2-butoxyethyl)phosphate, a plasticizer once used in Vacutainer stoppers, can displace basic drugs

**Figure 1** Loss of radiolabeled trifluoperazine from aqueous solution to different materials, as a function of time.

from protein-binding sites and that in the case of nortriptyline this resulted in reduced plasma concentrations as the displaced drug partitioned into erythrocytes. The plasticizer ethylhexylphthalate has been shown to increase the liquid extraction of zimelidine by adduct formation.

The container should not crack, nor should its stopper come off, during expansion of the contents due to freezing and thawing and other pressure changes, e.g., in aircraft holds. Generally, screw caps are preferable to push-fit stoppers. It is sensible to arrange samples in logical groups and to pack them in outer containers that minimize the risk of cross-contamination should a number of containers fail. In pharmacokinetic investigations, is it better to lose samples from one subject or all the samples at one time point? Tubes containing frozen samples should be inspected for damage before thawing. Naturally, the shape and size of the container must be suitable for its purpose. Psychiatric in-patients have been known to produce in excess of 2.5 l of urine a day. Human feces may be collected in polythene bags lining a suitable vessel to aid collection.

Irrespective of the nature of the container, the labels must remain firmly attached even when wet or during cold storage. The information must still be legible, and special marker pens may have to be issued. Preprinted labels can be used, but then one is reliant on the sample being put in the correct tube.

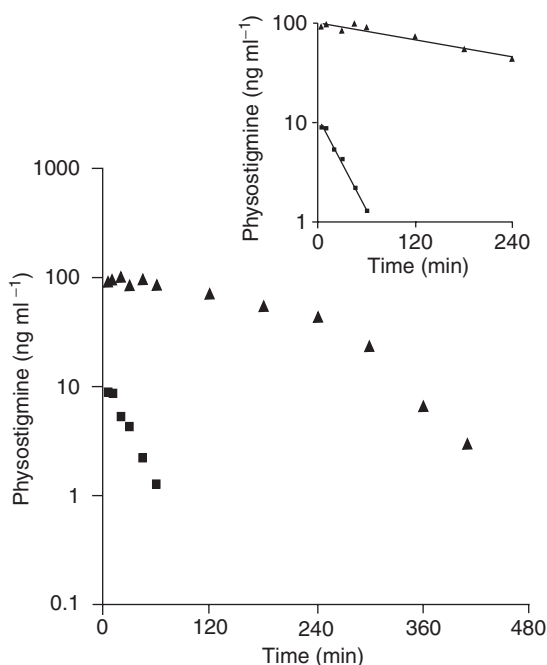

## Temperature

Generally samples are stored frozen at  $-20^{\circ}\text{C}$ , but lower temperatures may be needed. Plasma esterases may still be active at this temperature, and  $-70^{\circ}\text{C}$  may be required. The effect of freezing and thawing must be considered. Obviously, red cells will be hemolyzed and fibrinogen will separate from plasma. These solids will have to be separated before sampling, and it is important to prove that the analyte does not bind to them. Protein binding is temperature dependent, and centrifuging blood at  $4^{\circ}\text{C}$  rather than  $24^{\circ}\text{C}$  has been shown to result in higher plasma phenytoin concentrations. The protein binding was reduced at the higher temperature and the nonbound form partitioned into the red cells. Stratification occurs when samples are frozen, and so, after thawing, the contents of tubes should be agitated before sampling. Obviously, liquid should not be withdrawn until the sample is completely thawed to avoid 'apple-jacking', but when dealing with a large batch of tubes the presence of ice in some tubes may be overlooked.

## Preservatives

If the analyte is known to be unstable, then it may be appropriate to add some form of stabilizer to prevent decomposition. For example, tubes for blood alcohol determination should contain sufficient sodium fluoride to produce a final concentration  $>1.5\%$  (m/v), as otherwise colonies of opportune bacteria and fungi may produce, or utilize, ethanol.

For compounds that are unstable at certain pH values, adjustment of the pH before storage would be advisable. Esters and, to some extent, amides are subject to enzyme hydrolysis and may be rapidly destroyed by plasma enzymes. Stability testing must be conducted at appropriate concentrations. The *in vitro* half-life of physostigmine in plasma at  $37^{\circ}\text{C}$  has been reported as 190 or  $\sim 15$  min. This discrepancy is easily explained as the studies used different initial concentrations of the drug, which exhibits pseudo first-order metabolism at concentrations  $<10\text{ ng ml}^{-1}$  (Figure 2). Since the therapeutic concentrations of physostigmine are generally below  $2\text{ ng ml}^{-1}$ , the lower concentration was more appropriate for the stability study. The loss of physostigmine can be prevented by collecting blood in tubes containing neostigmine or pyridostigmine to produce a final concentration of  $10\text{ mg l}^{-1}$ . An advantage of using the quaternary ammonium compounds is that they are not extracted into organic solvents. Cocaine is similarly lost from plasma, and excess physostigmine has to be used to stabilize samples. Silver

**Figure 2** Effect of initial concentration on the kinetics of *in vitro* hydrolysis of physostigmine from human plasma at  $37^{\circ}\text{C}$ . From initial concentrations of  $10\text{ ng ml}^{-1}$  (■) and  $1\text{ ng ml}^{-1}$  (data not shown), the kinetics are pseudo-first-order ( $t_{1/2} \approx 19\text{ min}$ ), whereas the kinetics of decay from  $100\text{ ng ml}^{-1}$  (▲) are best described by the Michaelis–Menten equation. Inset: erroneously fitting the initial part (0–240 min) of the  $100\text{ ng ml}^{-1}$  data to a single exponential gives an apparent half-life of 210 min. Therapeutic concentrations of physostigmine are generally below  $2\text{ ng ml}^{-1}$ . (Reproduced with permission from Hurst PR and Whelpton R (1989) Solid phase extraction for an improved assay of physostigmine in biological fluids *Biomedical Chromatography* 3: 226–232; © John Wiley & Sons Ltd.)

nitrate can be used to prevent enzyme hydrolysis of glyceryl trinitrate and its dinitro metabolites. If the nature of the reaction is known, then specific inhibitors may be chosen, for example the use of the monoamine oxidase inhibitor pargyline during catecholamine assays.

Antioxidants such as ascorbate and metabisulfite have their place, but should not be added indiscriminately. Many tertiary amine drugs are metabolized to amine oxides that will be reduced by such antioxidants, not only elevating the concentration of the parent compound but often also resulting in some dealkylation to secondary amines, thus producing a spurious pattern of compounds. It should be noted that N-oxides and other oxides of nitrogen tend to be labile in alkaline solutions and prolonged exposure to high pH during sample preparation may cause problems, particularly in the presence of biological materials.

## Strategies for Sample Preparation

The methods chosen for sample preparation depend to a large extent on the overall strategy. The nature of the analyte, the required sensitivity, the type of sample matrix, the number of samples to be assayed, and the time and resources available will influence the choice. Before deciding on an approach, several questions need to be answered. Is the drug stable (chemical, thermal, light), volatile, reactive, lipophilic, or ionic? Is it bound to proteins and does it partition into erythrocytes? How is it to be quantified? What is the required sensitivity and how difficult will it be to meet that requirement? If the drug is metabolized, will the metabolites be in the sample, and are they to be assayed? Might metabolites interfere with the quantification? Questions concerning the matrix include 'Is it liquid or solid?', 'Is it homogeneous?', 'Will it contain other drugs or interferences?', and 'Will the sample volume be restricted?' Answers to questions concerning the number of samples and from where they originate will influence whether samples are to be assayed almost immediately or whether they will go into storage. If samples are to be stored, then the effects of storage time and temperature will have to be investigated.

The answers will exclude certain assay procedures, e.g., if the analyte is heat labile, then gas chromatography is usually inappropriate, as is evaporating an extraction solvent at elevated temperatures. If the concentration is high, or a particular assay is sensitive, then sample preparation may be minimal. On the other hand, trace amounts of analyte may require a complex assay procedure with multiple concentration and cleanup steps.

A method should be designed to be as simple as possible. Analysts should ask themselves why they are doing the assay. If the samples are the result of a multicenter trial that has generated hundreds, if not thousands, of samples, then throughput and method stability are paramount, and time spent in method optimization is justified. If a drug is to be measured only occasionally, then one should consider if it could be measured using a method currently in use, e.g., a gas chromatography (GC) method with a temperature change or an HPLC method with a change in detector wavelength. For the occasional sample, long retention times may be tolerable. If a method includes gas or thin-layer chromatography, then liquid extraction should be considered. It may be possible to inject a sample of the organic phase, or it may be necessary to evaporate it. Liquid-liquid extraction is usually appropriate if the analyte is to be derivatized. Solid-phase extractions are suitable for HPLC methods as the drug is usually eluted from

the cartridge with an eluent compatible with HPLC mobile phases.

### Direct Injection

For samples at high concentration or in relatively pure solution, it may be possible to assay the samples with minimal work-up. Some samples may simply need dissolving in a suitable solvent or diluting before analysis. Sometimes blood and plasma samples can be treated this way. Blood ethanol concentrations have been determined by adding blood to an aqueous solution of an internal standard (*n*-propanol) and injecting onto a GC column packed with Porapak-Q. Similarly, volumes of plasma containing sulfadimidine can be mixed with an equal volume of internal standard solution and centrifuged and a portion injected onto a C-18 HPLC column. By preparing the internal standard solution with twice the concentration of organic modifier as in the HPLC phase, the injection solution is compatible with the HPLC eluent, thus reducing the risk on precipitation of the column.

### Protein Precipitation

For plasma or blood samples in which the analyte concentration is high but which cannot be sampled directly, protein precipitation may be a suitable approach. Several agents have been used, the more efficient being acids those such as trichloroacetic, perchloric, metaphosphoric, and tungstic acids, which can be added as concentrated solutions so as not to dilute the sample unduly. The analyte must be stable at low pH values. As the supernatant is aqueous, this approach is best used with HPLC. Acetonitrile, methanol, or acetone may be more suitable for precipitating proteins when the analyte is acid labile. Also, these organic solvents may be preferable prior to GC analysis as they are easily evaporated and generally compatible with GC phases. Whatever agent is used, the risk of co-precipitation of the analyte must be assessed. For some drugs precipitation may be the first step, followed by purification and concentration by liquid-liquid extraction or solid-phase extraction (SPE).

### Liquid-Liquid Extraction

Although liquid-liquid extraction is an old technique, correctly applied, it remains one of the most useful. Generally it is best to use the least polar solvent that will effectively extract the drug. The nonpolar solvents *n*-heptane, cyclohexane, and toluene should be examined first, and if these prove unsuitable, then diethyl ether, ethyl acetate, and

chloroform can be considered. There is usually no advantage in selecting a solvent with too much 'extracting power' as this may reduce the selectivity of the assay by promoting the extraction of interfering compounds. The density of the solvent may be important; if large volumes of organic solvents are to be used and the phases separated in a separating funnel, then chlorinated solvents with densities  $> 1$  might be chosen. (Chlorinated solvents may be used with phase separating filter paper, although centrifugation to break any emulsion is required prior to use.) If the extraction is performed in tubes, it is usually better to have the solvent as the upper layer to facilitate removal. By mixing solvents, e.g., ether/chloroform, a polar extraction solvent that 'floats' can be obtained. An alternative is to add sufficient salt to the aqueous phase so that it is denser than the organic one. Potassium carbonate has been added to an aqueous solution containing acetonitrile to 'force' an organic layer to form.

If the organic solvent is to be evaporated, then a low boiling point may be an advantage, and hexane may be preferable to heptane, for example. However, very volatile solvents present handling difficulties. Evaporation of diethyl ether during sample transfers can result in extraction efficiencies that are apparently  $> 100\%$ , if appropriate corrections are not made. Under these circumstances the judicious use of an appropriate internal standard is recommended.

A further consideration is whether the solvent is likely to interfere with the analysis. Toluene is a poor first choice for a method that is to quantify the drug by ultraviolet detection. It is difficult to remove all traces of the solvent, and even a small residual amount can affect the detection limit seriously. Similarly, chlorinated solvents are best avoided if radioactive scintillation counting or electron-capture detection is to be used. Some solvents may not be suitable because they would react with the analyte, for example a ketone such as ethyl methyl ketone would react with primary amines. Solvent impurities and additives may be unknown to the analyst. Antioxidants such as hydroquinone and pyrogallol are added to diethyl ether to limit peroxide formation. These highly electroactive molecules can affect electrochemical detection methods adversely, particularly if they have been concentrated by solvent evaporation. Freshly distilled diethyl ether may be used, but it should not be stored as this is not only potentially dangerous, the peroxides that form may decompose the analyte. Methyl *t*-butyl ether (boiling point  $55^\circ\text{C}$ ) is supplied without antioxidants and is a useful alternative to diethyl ether. Chloroform and dichloromethane may be stabilized with ethanol although pentene is used by at least one manufacturer and may

be preferred for some applications. Impurities are a similar cause for concern: even with the addition of stabilizers, low concentrations of peroxides and phosgene have been known to present problems. Isovaleraldehyde, an impurity in isoamyl alcohol, has been shown to react with primary amine metabolites of chlorpromazine.

### pH-Controlled Extraction

The extraction of a weak acid or base into an organic phase is a function of the pH of the aqueous solution, the  $pK_a$  of the analyte, and the partition coefficient describing the distribution of the analyte between the particular solvent and water. Under ideal conditions, the fraction extracted,  $F$ , is given by

$$F = [1 + V_{\text{aq}}/(V_{\text{org}}\text{APC})]^{-1},$$

where  $V_{\text{aq}}$  and  $V_{\text{org}}$  are the volumes of the aqueous and organic phases, respectively, and APC is the apparent partition coefficient of the analyte. APC is a function of the true partition coefficient (TPC) (i.e., the partition coefficient of the nonionized form that is extracted),

$$\text{TPC} = [1 + 10^{(pK_a - \text{pH})}]\text{APC}$$

for a base or

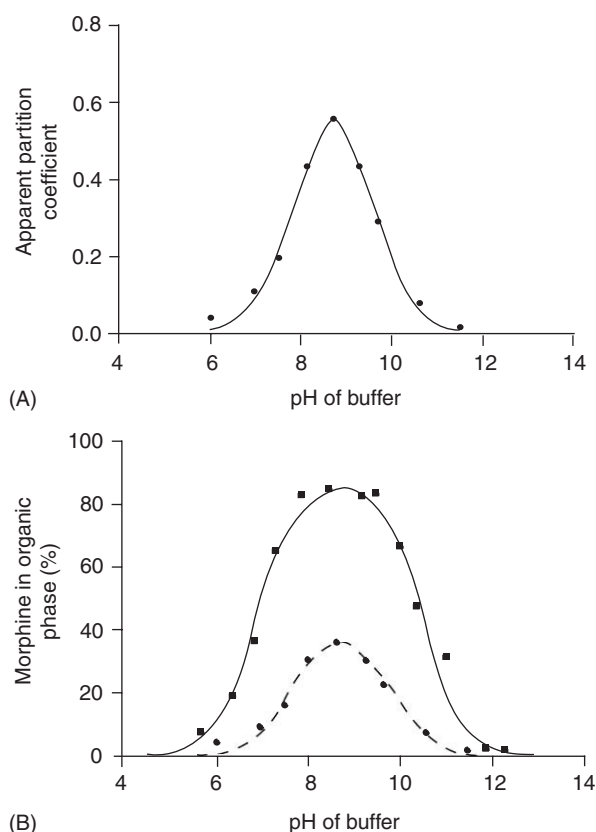

$$\text{TPC} = [1 + 10^{(\text{pH} - pK_a)}]\text{APC}$$

for an acid. Thus, the fraction extracted can be calculated from knowledge of pH,  $pK_a$ , and TPC. Usually, TPC for the particular solvent system is unknown, and the  $pK_a$  may be unknown or in doubt. However, these can be derived from iterative curve fitting of the experimental data, plotted as APC versus pH (Figure 3A). The advantage of this is that once the parameters are known, the extraction recoveries can be predicated for any organic:aqueous volume ratios for any pH value (Figure 3B). A day's experimentation allows optimization of extraction pH, solvent volume, and pH required for back-extraction into a predefined volume of aqueous phase. If a method is to be modified, the effect of a change in experimental conditions can be calculated in a few minutes.

### Ion-Pair Extraction

Ionized drugs can be extracted into organic solvents, provided an ion of the opposite charge (counterion) is extracted to maintain electrostatic neutrality. For a cation,  $C^+$ , being extracted as an ion-pair with a suitable anion,  $A^-$ ,

**Figure 3** pH-partition characteristics of morphine. (A) Partitioning of [ $^3\text{H}$ ]morphine between buffers and an equal volume of toluene–butanol (9:1 v/v). The data were fitted to the equations described in the text, using Graph Pad Prism v3, to give  $\text{TPC} = 0.62$ ,  $\text{p}K_{\text{a}1} = 7.77$ ,  $\text{p}K_{\text{a}2} = 9.69$  (solid line). (B) Comparison of predicted (solid line) and actual extraction of morphine assayed by liquid chromatography (■) for a 10:1 volume ratio of organic solvent:aqueous phase. The data of A plotted as percent extracted (—●—).

The distribution ratio,  $D_{\text{C}}$ , is given by

$$D_{\text{C}} = [\text{C}_{\text{org}}]/[\text{C}_{\text{aq}}] = E_{\text{CA}}[\text{A}_{\text{aq}}^-]$$

where  $E_{\text{CA}}$  is the equilibrium constant. Thus, the distribution is a function not only of the nature of the analyte and the extraction solvent but also the nature and concentration of the counterion. The partitioning can be further affected by introducing a substance with which the analyte is able to complex. This makes ion-pair extraction versatile and also complicated. Ion-pair extraction may be used with SPE columns – although interactions with cationic or anionic solid phases may result in a simpler approach.

It is worth noting that aberrant partitioning in liquid–liquid extraction can sometimes be explained by unintentional ion-pair extraction, the counterions arising from the buffer or biological matrix. Therefore,

unless ion-pair extraction is required, solvents that promote ion-pair extraction are best avoided.

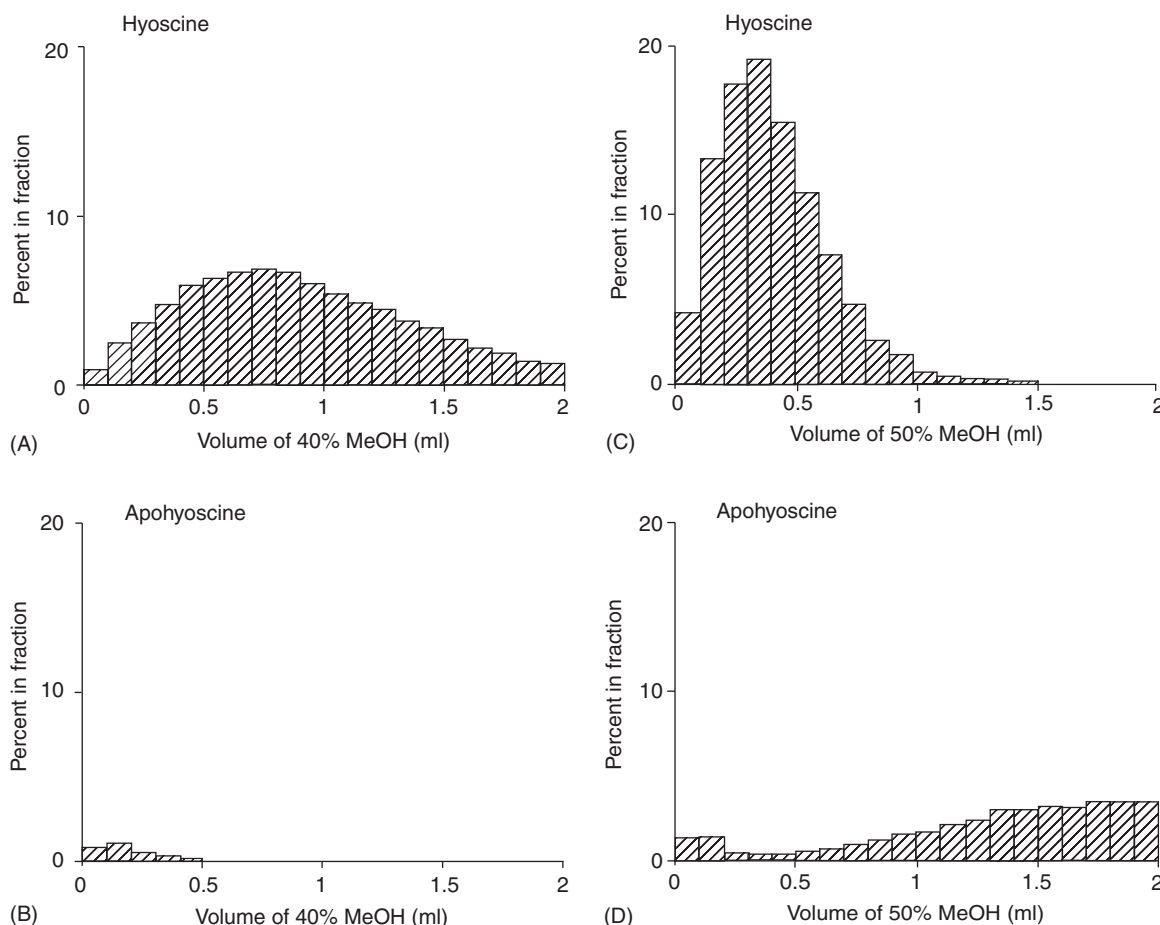

### Solid-Phase Extraction

SPE continues to be popular for sample preparation prior to analysis. Recoveries exceeding 95% with correspondingly low relative standard deviations are possible, and subnanogram quantities of analyte have been assayed without difficulty. It is particularly useful for drugs that are difficult to extract using liquid extraction, for example quaternary ammonium compounds such as pyridostigmine and (+)-tubocurarine and other hydrophilic compounds such as glucuronide metabolites. Because ionic forms can be extracted, it is possible to develop SPE methods that do not require such extreme pH values as required by liquid extraction, which makes SPE suitable for pH-sensitive drugs. Furthermore, it should be possible to perform SPEs in an inert atmosphere, by using syringes to load and elute samples or nitrogen to provide positive pressure to SPE columns.

Trace analysis, the ability to concentrate a drug and its metabolites from a large volume of fluid, is easily accomplished with SPE, and frequently, the compounds of interest can be eluted in a small volume of fluid. Even if the resulting eluate contains interfering substances, the reduced volume allows easier sample handling, e.g., smaller extraction volumes, during subsequent cleanup stages.

Once the analyte has been retained, a range of washing procedures is possible. Water may be used to remove residual hydrophilic materials, including proteins and buffer. Water–organic solvent mixtures may be applied to remove interfering substances and finally a suitable eluent to recover the analyte(s). If the minimum volume of eluent is used, then further concentration may be unnecessary. By careful choice of wash solutions, it may be possible to separate the drug, not only from endogenous interferences but from its metabolites. **Figure 4** shows the elution of hyoscyne and a metabolite, apohyoscyne, from a C-18 SPE column using 50% methanol. Over 90% of the hyoscyne was eluted in the first milliliter, whereas less than 5% of the metabolite was in this fraction. This example is a little unusual in that the metabolite is less polar than the parent and so is retained in preference to the parent drug. Generally metabolites would be expected to elute first from reversed-phase materials.

The continued development of SPE has led to an almost bewildering choice of column geometries and chemistries. The realization that ‘secondary’ interactions with residual silanol groups play an important, and sometime subtle, role in many SPE methods has

**Figure 4** Elution patterns of hyoscine (scopolamine) and its dehydrated metabolite, apohyoscine, from  $C_{18}$  SPE columns. Hyoscine (A) or apohyoscine (B) eluted with 40% (v/v) methanol:water and hyoscine (C) or apohyoscine (D) eluted with 50% (v/v) methanol:water. The latter eluent was chosen for the assay as >90% of hyoscine was recovered in the first milliliter, whereas <5% of the apohyoscine was eluted in this volume. Washing with 20% (v/v) methanol removed the majority of the urinary pigments but not the hyoscine. (Reproduced with permission from Whelpton R, Hurst PR, Metcalfe RF, and Saunders SA (1992) Liquid chromatographic determination of hyoscine (scopolamine) in urine using solid phase extraction *Biomedical Chromatography* 6: 198–204; © John Wiley & Sons Ltd.)

resulted in manufacturers offering a greater choice of phases, with popular columns being available in end-capped and non-endcapped versions, as well as columns with monofunctional bonding of the phase. Extending the concept of more than one type of interaction, mixed-mode columns utilize two or more primary retention mechanisms. The combination of nonpolar and ion exchange materials allows efficient washing to remove nonpolar impurities, without the risk of eluting the compounds of interest prematurely. This is exemplified in Figure 5, which illustrates a 'generic' method for bases, including quaternary ammonium compounds. Such an approach will appeal to those involved in drug development, where several candidate molecules have to be assayed and it is clearly not cost-effective to produce specific methods for each one. To increase throughput even more, the

numbers of samples that can be handled has been increased by adoption of 96-well plate technology (Figure 6) and robotics.

SPE is also moving in the other direction, with moves to make columns much more specific, with the development of antibodies bound to columns, and molecularly imprinted polymers (MIPs), an approach referred to as predetermined selectivity. Once polymerized, the template molecule must be removed from the polymer by extensive washing if high sensitivities are to be achieved; otherwise, there is the danger of the residual template molecule interfering in the assay. It has been suggested that a homolog of the drug to be analyzed should be used as the template molecule, and providing drug and homolog can be separated in a subsequent chromatographic procedure, then leaching of traces of template from the

**Figure 5** A 'generic' method for extraction of bases using a mixed-mode phase. The use of the strong cation exchanger allows rigorous washing with methanol to remove interferences, prior to elution of the analytes with alkaline ethyl acetate. (Reproduced with permission from *General Approach to the Extraction of Basic Drugs from Biological Fluids Using ISOLUTE<sup>®</sup> Confirm HCX Mixed Mode SPE Columns*, Application note – TN113 rev 1.1 (2001); © Argonaut Technologies. **Figure 6** Photograph of a 96-well ISOLUTE Array<sup>®</sup> SPE system (ISOLUTE is a trademark of Argonaut Technologies). (Courtesy of Argonaut Technologies, used by permission.)

column will not be a problem. However, if such an approach works, then one must question the specificity of the MIP. A further problem is that retention by MIPs is affected by the nature of the incubation medium. It is possible to have MIPs custom synthesized, and although this requires an initial high expense, the added specificity, when coupled with a large numbers of samples to be analyzed, may make this approach cost-effective. Other specialized approaches include use of antibodies bound to SPE phases (immunoaffinity SPE), for example.

SPE is not without its difficulties. An obvious disadvantage is that particulate material in the sample will block the column frits so that sample types are

limited. Tissue homogenates are unsuitable unless the analytes are in the supernatant liquid after centrifugation. It is advisable to filter or centrifuge samples (after any pH adjustment) before they are applied to SPE columns. A white gelatinous precipitate is frequently formed when urine is made alkaline, and so methods in which buffer and sample are added to the column reservoirs are best avoided. Blood can be assayed provided the erythrocytes are disrupted, e.g., by freezing. There is little cell debris, and so after centrifugation, ~90% of the sample can be added to the columns.

The recoveries from biological materials may differ, not only between sample types but within a sample type. This may mean that a method optimized using water or a different sample type will have to be modified, possibly by the use of a more retentive column at the expense of selectivity. With some drugs, recoveries from urine appear to be related to the concentration of the sample: deep yellow samples give lower recoveries than paler ones. Reduced recoveries with plasma or serum may be indicative of plasma protein binding competing with binding to the solid phase. For example, the retention of buprenorphine from plasma on C-18 extraction columns was 33%, 90%, and 95% at flow rates of 10, 1, and 0.1 ml min<sup>-1</sup>, respectively. When the buprenorphine was applied in water, the retention was >97%, irrespective of the flow rate through the column. Increasing the capacity of the column, reducing the flow rate to allow equilibration with the solid phase, and disrupting the binding, e.g., with a small amount of ethanol or diluting the sample, say, 10 times with water, may be necessary. An alternative

approach to avoiding variable recoveries due to protein binding is to combine LLE and SPE.

Note that because of the trace enrichment capabilities of SPE, it is only a small inconvenience to dilute the sample if need be. However, impurities in water and buffer solutions may be retained, and so it is important to ensure they are pure – even to the extent of passing them down suitable SPE columns prior to use.

### Solid-Phase Microextraction

Solid-phase microextraction (SPME), initially introduced for analysis of environmental samples, has been increasingly used for extraction of drugs from biological matrices. In its simplest form, a solid probe (originally a fused silica fiber) coated with a polymer film is inserted into the sample containing the analyte, which is subsequently thermally desorbed in a hot injection port, in the case of GC or GC–mass spectrometry quantification, or in a desorption interface, in the case of HPLC analysis. Thus, the drug partitions between the sample, usually aqueous, and the liquid phase supported on the fiber, usually polydimethylsiloxane, polydimethylsiloxane–divinylbenzene, or polymethacrylate. Unlike liquid–liquid extraction, described above, the aim is not to extract all the analyte from the sample as this is an equilibrium extraction; indeed the concentration of the sample may be little affected if only a very small proportion of drug is removed. Obvious attractions of SPME are that no solvents are required and all the material that is extracted by the probe is injected for analysis.

When acids or bases are extracted, it is normally necessary to buffer the pH of the sample to increase the proportion of unionized drug to optimize the extraction. Salting out may be employed to increase the proportion of drug extracted. Differences in the ionic strength of urine samples may lead to variable recovery unless the samples are brought to similar ionic strength by addition of excess salt. Increasing the temperature usually reduces the time to reach equilibrium but will also reduce the amount extracted. Potential disadvantages include competition between drug and endogenous compounds for the fiber, particularly when the mechanism is adsorption rather than partitioning. A well-chosen internal standard (preferably isotopically labeled) may be required to ensure that the method is sufficiently robust. It is important to define the time required for equilibrium, and protein binding is likely to have more of an effect on recovery than when practically all the analyte is extracted into an organic phase. Plasma protein binding not only reduces the amount of

**Figure 7** Time-course for the extraction of lignocaine (lidocaine) from plasma samples after buffering 1:1 to pH 9.5 (A) with and (B) without deproteinization. The solid lines represent the least-squares fit to Peak Area = Maximum Peak Area  $(1 - \exp(-kt))$ . Note how protein binding affects both the rate of attainment of equilibration and the maximum amount that can be extracted (broken lines). (Reprinted with permission from Koster EH, Wemes C, Morsink JB, and de Jong GJ (2000) Determination of lidocaine in plasma by direct solid-phase microextraction combined with gas chromatography. *Journal of Chromatography B* 739: 175–182; © Elsevier.)

analyte extracted, it also increases the time for equilibration. When the data of Figure 7 are fitted to exponential curves,

$$X_t = X_m[1 - \exp(-kt)]$$

where  $X_t$  is the amount extracted at time  $t$ ,  $X_m$  is the maximum amount that can be extracted at equilibrium, and  $k$  is the first-order rate constant, then the half-lives (derived from  $t_{1/2} = 0.693/k$ ) with and without deproteinization are 6.1 and 13.8 min, respectively. Because  $>95\%$   $X_m$  is attained in five half-lives, with deproteinization equilibration was reached in  $\sim 30$  min, whereas to reach the same degree of equilibration in the nondeproteinized sample would take 70 min. If the time for desorption and analysis is similar to, or longer than, the time required for extraction, then one sample can be extracted while the previous one is being analyzed.

The high initial cost may deter some laboratories from automation of sample preparation, but whether automated or not, liquid–liquid extraction and SPE are almost certainly going to remain the most widely applied sample preparation techniques for the foreseeable future. A good understanding of the principles involved will ensure that they are applied in the most appropriate way.

## Pharmaceutical Plant Extracts

The role of herbal medicinal products (HMPs) is growing not only in self-medication but also in medical practice, and the expectations related to their quality, safety, and efficacy, which represent the precondition for obtaining an authorization for marketing as medicinal products according to Directive 2001/83/EC, have increased hugely.

The first 'Guidelines for the assessment of herbal medicines' were published by the World Health Organization (WHO) in 1991, handing down the basic principles for the analysis of plant preparations (herbal drug preparations, HDPs) and the finished products prepared from these (HMPs): "A method for identification and, where possible, quantification of the plant material in the finished product should be defined. If the identification of an active principle is not possible, it should be sufficient to identify a characteristic substance or mixture of substances (e.g., 'chromatographic fingerprint') to ensure consistent quality of the preparation."

Subsequently, the European Commission and the European Agency for the Evaluation of Medicines (EMA) pushed forward harmonization of the

assessment criteria for herbal medicinal products. The Herbal Medicinal Products Working Party (HMPWP) of the EMA developed the Note for Guidance 'Quality of Herbal Medicinal Products', adopted by the Committee for Proprietary Medicinal Products (CPMP) in 2001, which includes the specifications for the profile and stability of the constituents.

Furthermore, the European Pharmacopoeia has up to now published 150 monographs on herbal drugs (HDs) and HDPs, including general monographs on extracts. They are classified:

- In terms of their physical state (liquid extracts including fluid extracts, tinctures, oil macerates, semisolid preparations called soft extracts, and dry extracts).
- In terms of the question of whether they only contain herbal extractable matter (native extracts) or additional excipients (not-native extracts = extract preparations).
- In terms of the knowledge relating to their therapeutically active constituents (adjusted/standardized, quantified, other extracts). Refined extracts are also reported and defined by the production process.

Standardized extracts contain constituents (single or groups) that are solely responsible for the acknowledged and documented therapeutic activity and the adjustment to a defined content is acceptable (e.g., standardized Senna leaf dry extract, Aloe dry extract, Belladonna leaf dry extract, Liquorice

## Pharmaceutical Plant Extracts

The role of herbal medicinal products (HMPs) is growing not only in self-medication but also in medical practice, and the expectations related to their quality, safety, and efficacy, which represent the precondition for obtaining an authorization for marketing as medicinal products according to Directive 2001/83/EC, have increased hugely.

The first 'Guidelines for the assessment of herbal medicines' were published by the World Health Organization (WHO) in 1991, handing down the basic principles for the analysis of plant preparations (herbal drug preparations, HDPs) and the finished products prepared from these (HMPs): "A method for identification and, where possible, quantification of the plant material in the finished product should be defined. If the identification of an active principle is not possible, it should be sufficient to identify a characteristic substance or mixture of substances (e.g., 'chromatographic fingerprint') to ensure consistent quality of the preparation."

Subsequently, the European Commission and the European Agency for the Evaluation of Medicines (EMA) pushed forward harmonization of the

assessment criteria for herbal medicinal products. The Herbal Medicinal Products Working Party (HMPWP) of the EMA developed the Note for Guidance 'Quality of Herbal Medicinal Products', adopted by the Committee for Proprietary Medicinal Products (CPMP) in 2001, which includes the specifications for the profile and stability of the constituents.

Furthermore, the European Pharmacopoeia has up to now published 150 monographs on herbal drugs (HDs) and HDPs, including general monographs on extracts. They are classified:

- In terms of their physical state (liquid extracts including fluid extracts, tinctures, oil macerates, semisolid preparations called soft extracts, and dry extracts).
- In terms of the question of whether they only contain herbal extractable matter (native extracts) or additional excipients (not-native extracts = extract preparations).
- In terms of the knowledge relating to their therapeutically active constituents (adjusted/standardized, quantified, other extracts). Refined extracts are also reported and defined by the production process.

Standardized extracts contain constituents (single or groups) that are solely responsible for the acknowledged and documented therapeutic activity and the adjustment to a defined content is acceptable (e.g., standardized Senna leaf dry extract, Aloe dry extract, Belladonna leaf dry extract, Liquorice

ethanolic liquid extract, Ipecacuanha tincture, etc.) using inert excipients or preparations with a higher or lower content. Quantified extracts are those containing chemically defined constituents (single or groups) possessing relevant pharmacological properties (active markers, e.g., the extracts of ginkgo and St John's wort). 'Other extracts' are those containing no constituents documented as being determinant or relevant for efficacy, or as having pharmacological or clinical relevance. They may be used for control purposes (e.g., *Matricaria* liquid extract, Valerian or Stinging nettle root dried extract).

## Pharmaceutical Aspects

The constituents of the extracts are generally represented by a complex mixture of compounds and it is practically impossible within quality assurance to take account of all constituents of an herbal extract, apart from the fact that in most cases the complete spectrum of constituents is far from being known or analytically detectable. Reproduction and control of a defined spectrum of constituents can only be based on those substances or groups of substances that, according to the state of scientific knowledge, are pharmaceutically, pharmacologically, or toxicologically relevant.

As a result, obtaining reliable chromatographic fingerprints that chemically represent pharmacologically active and characteristic components is not trivial work and determining their pharmaceutical quality can be a difficult and complicated process. The quality of the chromatographic fingerprint obtained is closely dependent on the degree of chromatographic separation and concentration distribution of all chemical components in the investigated extract.

If the active principle or the group of active substances in the extract has been identified – such as reserpine in *rauwolfiae* extract or anthraquinones in senna extract – then the other substances contained are, at least from the point of view of the analyst, considered to be of secondary importance. These extracts have a permitted variability of the defined range of constituents and it should not exceed a numeric difference of  $\pm 5\%$  (more than  $\pm 5\%$  in rare cases).

Very often, however, the situation is more complicated in that many unrelated substances (single or groups) may be involved in the pharmacological efficacy of a particular extract. Flavonoids, sesquiterpenes (bilobalide), and diterpenes (ginkgolides) are all endowed with the biological activity of ginkgo extracts, while flavonols, naphthodianthrone, and phloroglucinols are related to the activity of St John's

wort extract. These extracts should generally be quantified by specifying a relatively wide spectrum of qualitative and quantitative aspects of the contents. The ratio of the weight of the processed drug and the weight of the resulting extract is of particular importance; the dose of the extract is frequently determined with a view to the efficacy of the original HD. Therefore, the standardization of extracts is not merely an analytical tool, but also involves the whole production process.

As plant extracts are pharmaceutical substances, they are subject to the same strict controls as other medications. Particularly high demands are placed on the validation of analytical methods.

Further problems are caused by the need for precision and accuracy. A method for determining accuracy would be to add a known quantity of the natural leading principle, but often this is simply not possible as the compound is not available in sufficient quantities.

Today, analytical chemistry offers the opportunity to investigate these problems in different ways using: chromatographic techniques, such as thin-layer chromatography (TLC), high-performance liquid chromatography (HPLC), or gas chromatography (GC); electrophoretic techniques, such as capillary electrophoresis (CE); or spectroscopic methods, such as mass spectrometry (MS), nuclear magnetic resonance (NMR), ultraviolet (UV), infrared (IR), or near-infrared (NIR).

However, the complete analysis of all the constituents of an extract such as the case of the flavonol glycosides in ginkgo extract would require the evaluation of more than 30 peaks in the chromatogram; thus, it is used in practice only for the qualitative verification of stability using comparative chromatograms. Simpler methods have been developed for day-to-day quality control to quantify the compounds. Thus, glycosides of ginkgo extract are hydrolyzed to form the three aglycones kaempferol, quercetin, and isorhamnetin, which are quantified by HPLC–UV detection at 370 nm. This procedure is also reported in the draft monographs on ginkgo leaf for the United States and European Pharmacopoeias.

## Extraction and Cleanup Procedures

Extraction, sample cleanup, separation, and detection of constituents should be described in detail and thoroughly validated, but unfortunately analytical procedures are rarely published as the manufacturers usually only make their methods known to the pharmaceutical licensing authorities.

The extraction procedures used most frequently in phytoanalysis are solid-liquid extraction (SLE),

solid-phase extraction (SPE), liquid–liquid extraction (LLE), and rarely reported supercritical fluid extraction (SFE). SLE solvents include methanol, ethanol, acetone, water, ethyl acetate, propanol, dimethylformamide, dichloromethane, and their combinations, while LLE needs two immiscible phases, such as ethylacetate/water or hexane/water.

SPE is used both for preconcentration and cleanup of analytical samples. It offers a great variety of different sorbents, which are based on silica, polystyrene, and pyrrolidone polymers and copolymers. SFE could be useful for the cleanup of essential oils before GC analysis or for less polar constituents such as ginkgo terpenes and kavalactones from kava-kava.

The advantages of this purification are reproducibility and automation.

### Spectroscopic and Spectrometric Methods of Analysis

UV–visible spectrophotometry has long been used in the analysis of extracts and is the preferred technique described in pharmacopoeias. The main problem is its lack of selectivity, but this can be turned into an advantage, especially when the identification of the chemical group to which the substance belongs makes it – in rare cases – possible to evaluate efficacy as in the cases of anthraquinones in the extracts

**Figure 1** Relevant parts of 200 MHz NMR spectra of (A) a sample of ginkgo leaves and (B) a sample of a pharmaceutical product. Solvent: acetone- $d_6$ –pyridine- $d_5$ –methanol- $d_4$  (18:6:1); internal standard: maleic acid; 128 scans. (Reproduced with permission from van Beek TA, von Veldhuizen A, Lelyveld GP, Piron I, and Lankhorst PP (1993) *Phytochemical Analysis* 4: 261–268; © Wiley.)

of laxative HDs or anthocyanins in bilberry extracts. This method avoids time-consuming separation and at the same time gives a significant spectrum of the whole fingerprint.

UV-visible spectrophotometry is still important for LC and CE detection of numerous important naturally occurring groups of substances, such as flavonoids, phenolic acids, anthraquinones, and coumarins, because they have very characteristic UV spectra.

NIR can also play an important role in phytoanalysis. There are some reports on the use of NIR for the quantitative analysis of water content, residual solvents of dry extracts, as well as for the analysis of constituents. It has been used in the analysis of polyphenols (wine, soy) and a quantitative NIR reflectance spectroscopy method was established for the determination of two major constituents of St John's wort (hyperforin and biapigenin) using HPLC as reference method. It was also successfully used for the rapid evaluation and quantitative analysis of essential oils using GC as reference method. It can be considered a rapid and highly effective alternative method to conventional quantitative analysis of plant extracts.

NMR is not frequently used for the direct analysis of plant extracts.  $^{13}\text{C}$  NMR spectroscopy, for example, is sometimes used in the identification of essential oils. Quantitative  $^1\text{H}$  NMR procedures for the determination of constituents are rarely reported but

could be truly useful because the selectivity, reproducibility, and sensitivity are comparable with HPLC, besides the great advantage that no reference substances are needed. Quantification of bilobalide and ginkgolides in ginkgo extracts and commercial phytopharmaceuticals (as reported in Figure 1), and studies on extracts of kava-kava, arnica, and St John's wort have been performed.

MS (electrospray ionization (ESI)-MS and matrix-assisted laser desorption ionization time-of-flight) can also be used as a qualitative analytical tool for the analysis of plant extracts. A typical sample of ESI-MS analysis of ginkgo extract is reported in Figure 2.

## Chromatographic Methods of Analysis

The development of chromatographic methods and especially of techniques coupled with different detectors during the last two decades has greatly aided the analysis of extracts.

### Capillary Gas Chromatography

Capillary gas chromatography has been found to be the most selective technique for the analysis of essential oils. This technique is now recommended in the European Pharmacopoeia as the standard method to analyze essential oils. The recommended stationary phase is poly(ethylene glycol) 20000. GC

**Figure 2** Positive ion mass spectrum of a ginkgo standardized extract introduced by direct infusion into an ESI-MS. Peaks at  $m/z$  349, 431, 447, and 463 correspond with  $[\text{M} + \text{Na}]$  for bilobalide, G-A, G-B, G-J, and G-C, respectively. (Reproduced with permission from Mauri P, Migliazza B, and Pietta P (1999) *Journal of Mass Spectrometry* 34: 1361–1367; © Wiley.)

is still underutilized for the determination of polar substances because of the necessity to form derivatives of the constituents. The phenolglycosides in willow bark can be detected as trimethylsilyl derivatives (reagent: trimethylsilylimidazole in pyridine) on an OV-1 fused-silica capillary column with high separation power and selectivity. Ginkgolide derivatives obtained with 1% trimethylchlorosilane in

*N,O*-bis(trimethylsilyl)trifluoroacetamide are separated with a 30-m capillary column coated with 100% dimethyl polysiloxane phase.

However, silylation of nonvolatile constituents represents the main disadvantage, in comparison to HPLC, while separation is at least similar. Detection by flame ionization (FID) surpasses any available LC detector in reproducibility, baseline stability,

**Figure 3** HPLC-ELSD profile of both acidic and neutral ginsenosides. Separation is performed on a Hypersil BDS C18 column using a step gradient of (A)  $8\text{ mmol l}^{-1}$  ammonium acetate, pH 7 with ammonium hydroxide and (B) MeCN. Peaks 1–25 are identified as neutral and malonyl ginsenosides, respectively. Rg<sub>1</sub> (1), Re (2), Ro (3), malonyl-Ra<sub>1</sub>/Ra<sub>2</sub> (4), malonyl-Rb<sub>1</sub> (5), malonyl-Rb<sub>2</sub>/Rb<sub>3</sub>/Rc (6), malonyl-Rb<sub>1</sub> (7), malonyl-Ra<sub>1</sub>/Ra<sub>2</sub> (8), malonyl-Rb<sub>2</sub>/Rb<sub>3</sub>/Rc (9), malonyl-Rb<sub>2</sub>/Rb<sub>3</sub>/Rc (10), Ra<sub>3</sub> (11), malonyl-Rb<sub>2</sub>/Rb<sub>3</sub>/Rc (12), Rf (13), malonyl-Rb<sub>2</sub>/Rb<sub>3</sub>/Rc (14), malonyl-Rd Notoginsenoside R<sub>2</sub>/F3 (15), malonyl-Rd Ra<sub>1</sub>/Ra<sub>2</sub>/isomer (16), Rb<sub>1</sub> (17), Rg<sub>2</sub> (18), Rc (19), Ra<sub>1</sub>/Ra<sub>2</sub>/isomer (20), Ra<sub>1</sub>/Ra<sub>2</sub>/isomer (21), Rb<sub>2</sub> (22), Rb<sub>3</sub> (23), Ra<sub>1</sub>/Ra<sub>2</sub>/isomer (24), Rd (25). ruggedness, cost, and sensitivity. Instead of FID, two other detectors can be used: electron capture (ECD) and MS. However, the slight increase in selectivity and sensitivity of ECD compared with FID is offset by the problems associated with this detector: not generally available, limited linear range, and its inherent radioactivity. GC-MS is only necessary when the concentrations are very low such as in the analysis of biological fluids.

### Liquid Chromatography

The development of numerous derivatives of silica gel with an apolar surface (reversed phase (RP)) as a stationary phase has revolutionized extract analysis and is still considered the most straightforward technique for high-melting, nonvolatile compounds.

In most cases, gradient elution is vital, as even small structural variations will cause considerable differences in retention times.

Spectrophotometric detection is generally used and the choice of solvents is limited to those with low absorption properties. Especially, acetonitrile, tetrahydrofuran, methanol, or isopropanol and, less commonly, dioxan (which can be used for the separation of cardiac glycosides and derivatives of amino acids) have been found to be sufficiently selective in most cases. Water is used to adjust solvent strength and the addition of acid (preferably orthophosphoric acid, although acetic and formic acids can be used, especially if MS detection is hyphenated) or buffer in RPLC will decrease peak tail. A typical sample of the use of an ammonium buffer is reported for the HPLC analysis of both neutral and acid ginsenosides (Figure 3).

Phenolic compounds and constituents with conjugate systems can be easily detected by UV because they have a maximum wavelength in the range 250–350 nm and some of them (anthocyanins) reach values in the range 450–550 nm. Problems caused by differences in the wavelength for maximum UV absorption by individual constituents such as in St John's wort can be solved by using diode array detection (DAD). In the developed HPLC-DAD method, the identification and quantification of 16 compounds of four different classes of constituents – flavonoids, phenolic acids, naphthodianthrones, and phloroglucinols – can be quantified (Figure 4).

UV detection of compounds having very low values around the nonselective wavelength of 210–220 nm is a poor choice and a much better approach is, therefore, a detector that shows less variation in response factors, e.g., refractive index (RI) detection or evaporative light scattering (ELS) detection. Examples of UV/RI and UV/ELS detection of ginkgolides are given in Figures 5 and 6, respectively.

Advantages of ELS detection over RI are better baseline stability, compatibility with THF and gradients, small solvent peak, and greater sensitivity. Advantages of RI over ELSD are larger linear range, lower costs, and its broader availability.

The only other LC detection technique used is MS. Atmospheric pressure chemical ionization and ESI interfaces are also employed in many extract analyses. These are highly sensitive and stable. However, although the MS detectors offer a high selectivity and sensitivity, due to their high cost and more complicated operation and maintenance they remain a method of choice for clinical studies of the metabolites of natural constituents.

**Figure 5** HPLC profiles of a purified ginkgo preparation with (upper trace) UV detection at 219 nm and (lower trace) RI detection. Separation is performed on a C-18 SPE column using a mixture of methanol–water (33:67) as eluent. BB is biolbalide, GJ, GC, GA, and GB are, respectively, ginkgolide J, ginkgolide C, ginkgolide A, and ginkgolide B. Internal standard (IS) is benzyl alcohol. **Figure 6** HPLC–UV and HPLC–ELSD profiles of a filtered methanolic extract of a ginkgo drug containing standardized extract. Separation is performed on a Phenomenex Synergi Max-RP 80 column using two solvents (A = 10 mmol l<sup>-1</sup> NH<sub>4</sub>OAc adjusted to pH 5; B = MeOH–iBuOH (9:1)) in a linear gradient program. Peaks 1–5 were identified as bilobalide, ginkgolide J, ginkgolide C, ginkgolide A, and ginkgolide B, respectively. (Reproduced with permission from Ganzera M, Zhao J, and Khan IA (2001) *Chemical Pharmaceutical Bulletin* 49: 1170–1173, The Pharmaceutical Society of Japan.)

### Supercritical Fluid Chromatography

Supercritical fluid chromatography is also capable of separating constituents of extracts, often with a higher selectivity than RPLC. There is a recent report on the analysis of ginkgolides on a deactivated aminopropyl silica column using 12% methanol in carbon dioxide as fluid with a baseline separation of bilobalide and all four ginkgolides achieved within 9 min. Detection was facilitated by an ELS detector and a detection limit of ~10 ng was reported without sample cleanup (Figure 7). Thus, SFC can be used as an alternative for the analysis of extracts even if in the near future it is unlikely to replace either HPLC or GC in the average quality control laboratory.

### Thin-Layer Chromatography

TLC is an essential aid to extract analysis and is commonly used for qualitative assays. As the planar method gives ‘two-dimensional’ results, it is ideal for the comparison of the raw material and the end-products. With a few notable exceptions, the main

goal of extract manufacturing is to ensure that substances extracted from the biological matrix reoccur in unchanged form in the resultant extract (see Figure 8). TLC is thus used primarily for identification purposes. G60 silica gel on glass or aluminum plates is widely recommended as the stationary phase.

It is instructive to concentrate on the flavonoids, as these are of primary importance in qualitative assays of several HDs. Silica gel as stationary phase and ethyl acetate–ethyl methyl ketone–formic acid–water (50:30:10:10 by volume) as mobile phase is used in the analysis of flavonoids with C-glycosides (hawthorn, passion flower), and a mobile phase of ethyl acetate–formic acid–acetic acid–water (100:11:11:27 by volume) is used as the basic solvent for O-glycosides (arnica, calendula, chamomille). Following spraying of the plates with 2-aminoethyldiphenylborinate (NTS, 1% in methanol) and subsequent treatment with poly(ethylene glycol) 4000 (PEG, 5% in ethanol), flavonoids display yellow to green fluorescence under UV irradiation at 365 nm. The frequently observed blue spots represent phenol

**Figure 7** SFC-ELSD profile of a methanol solution of a standardized ginkgo extract without any prior sample cleanup. Separation is performed on a Deltabond PEG column using CO<sub>2</sub> with 12% modifier (MeOH) at 280 atm and 40°C. BB is biolbalide, GJ, GC, GA, and GB are, respectively, ginkgolide J, ginkgolide C, ginkgolide A, and ginkgolide B. carboxylic acids, which often occur in HDs that are rich in flavonoids.

Quantitative analysis with the aid of densitometry is not yet in general use in extract analysis. Various problems are present as the separation potential of the thin layer is limited.

### Capillary Electrophoresis

CE is a relatively new separation technique compared to GC and HPLC. It offers the advantages of rapid, high-resolution separation. The instrumentation format of CE is similar to HPLC and therefore most of the detectors used for HPLC can be adapted to CE.

Owing to the rising cost of solvent disposal, CE is becoming a more attractive method for extract analysis. The method makes it easy to separate ionizable substances using minimal amounts of solvents. On-column detection removes the coupling problems, and the separation power is comparable to that obtained in capillary gas chromatography. If alkaloids have to be analyzed, this method is currently the most suitable.

*Uncaria tomentosa* alkaloids can be separated using a phosphate buffer with a pH of 5–6 using 10 kV. Fused-silica capillary tubes with an internal diameter of 50–100 µm and a length of approximately 1 m are positioned in the electric field and loaded with the sample. Recently, CE has also been used for quantitative determination of glycyrrhizinic acid in pharmaceutical preparations using borate buffer at a pH of 10 using 25 kV. The method has also been used for the analysis of flavonoids and phenolic acids of echinacea extracts (see **Figure 9**), where the charge required for transport in the electrical field was produced using a micelle (micellar electrokinetic chromatography). Sodium dodecyl sulfate micelles are prepared in a sodium borate buffer for the separation of the various polyphenols. High-resolution separation and versatility of CE are reported in all studies.

### Stability Problems

It is impossible to make generalized statements about the stability of plant extracts: each has its own individual properties in this regard and, above all,

stability is related to chemical, microbiological, and physical stability. However, according to HMPWP guidelines, 'Quality for HMPs', the acceptable ranges of the constituents, related to the initial value are  $\pm 5\%$  if the product contains an HD or HDP with

**Figure 8** Thin-layer chromatography of *Hypericum perforatum*. The chromatograms show no important differences between the herbal drug and the extract except the red spots in front. Both spots are the result of chlorophyll, which is eliminated by the extraction procedure. Red spots: Hypericin and pseudohypericin; yellow and orange spots: flavonoids (glycosides R, 0.5; aglycones R, 0.8); blue spot: ubiquitous plant acids. Reference traces on the left: Hypericin; chlorogenic acid; and quercetin. (Reproduced with permission from Beat Meier, Zeller AG, Herbal Remedies, Romanshorn, Switzerland.)

known active constituents, and  $\pm 10\%$  if the active constituents are not known.

Generally, glycosides undergo hydrolysis to become the corresponding aglycones, so it is possible to evidence the transformation over time by appropriate fingerprinting making a comparison between the stored finished product and the dry extract. A typical example is represented by the complex mixture of flavonoids of ginkgo preparations (Figure 10).

The stability of natural compounds is quite variable. Salicin, in drug form and also in the form of its esters salicortin and tremulacin, is stable over several years in willow bark and extracts. Kavalactones from kava-kava extracts and preparations are stable for several years as well. The fact that essential oils are very volatile means that they are never major constituents in dry extracts unless they are added later in a stabilized form, for example, as microcapsules. Some important plant constituents are very sensitive to temperature. The content of naphodianthrones and phoroglucinols in St John's wort extracts and preparations are very sensitive to light, humidity, and temperature. Alliin in garlic will fall dramatically if the extract is stored at temperatures of  $30^{\circ}\text{C}$ . The second main problem with dry extracts is not so much their chemical stability as their actual physical stability: most dry extracts are hygroscopic and tend to absorb water. Thus, it is essential that they are stored away from heat and moisture. The stability of fluid extracts is somewhat more problematic than that of dry forms; it should also be kept in mind that not only chemical but also enzymatic degradation is

**Figure 9** Representative electropherograms obtained from: A, collected *E. purpurea* roots; B, commercial dried extract of *E. purpurea*; and C, commercial product. MEKC conditions:  $40\text{ mmol l}^{-1}$  sodium tetraborate pH 9.2 with  $70\text{ mmol l}^{-1}$  sodium deoxycholate. **Figure 10** Stability test of a ginkgo full extract with fingerprint chromatography. Separation is performed on a Phenomenex Synergi Max-RP 80 column using three solvents (A = water–85% phosphoric acid (95:5 v/v); B = *i*-propanol–THF (27.8:72.2 v/v); C = AcCN) in a linear gradient program. Peaks are detected at 350 nm. After storage for 6 months (at room temperature) no differences in the upper trace (liquid preparation) and the lower trace (standardized extract), with permission from Elsevier Science.

possible. There are enzymes, such as the glycosidases, that are surprisingly robust and can suddenly become active under the most disadvantageous conditions. If stability improves significantly following heat treatment, it is more than likely that enzymes are involved.

However, according to the HMPWP guideline for the evaluation of extract stability “it must be shown, as far as possible, e.g., by means of appropriate fingerprint chromatograms, that other substances present in the herbal drug or in the herbal drug preparation are likewise stable and that their proportional content remains constant.” Thus, unknown substances that very often represent the main part of the extract can undergo degradation so that specific chromatographic methods of analysis may not suffice. For this reason NMR, both using one-dimensional experiments, such as  $^1\text{H}$  and  $^{13}\text{C}$ , and two-dimensional experiments, could be useful to have a general overview of the whole extract and evaluate the stability of the preparation.

## Pharmacological Interpretation of Data

The chromatographic profile should feature the fundamental attributions of ‘sameness’ and ‘differences’ of the constituents of the investigated extract and define their quality in order to get reproducible biological data in terms of safety and efficacy. The analytical methods should be so precise that different batches of the extract in question will have the same efficacy. As described above, it has now become routine to define a ginkgo extract in terms of the content of the two groups, the flavonoid glycosides and

ginkgolides. The quality of optimized chamomille extracts should be defined at least in terms of the flavone apigenin, of chamazulen, and of  $\alpha$ -bisabolol contents, if the preparation is mentioned for the therapeutic activities of *Matricaria chamomilla*.

A great deal of research into potential synergistic effects still needs to emerge. These studies can only be conducted in living organisms and require considerable resources, while results themselves are difficult to interpret. However, there is plenty of evidence to suggest that synergistic reactions do occur. Standard biological *in vitro* and *in vivo* methods (e.g., using isolated cells or microorganisms) for defining plant extract quality are therefore still in the process of being developed. Some current methods use, for example, antiviral activity, inhibition of platelet-activating factor (which induces thrombocyte aggregation in rabbit plasma rich in platelets), inhibition of cyclooxygenase in sheep seminal vesicles and of 5-lipoxygenase in porcine leukocytes, or inhibition of cholesterol biosynthesis in cultured human and rat hepatocytes. There is often a correlation between the characteristics of the active principle as defined by analysis and the postulated pharmacological effects of the HDs. However, as many active agents extracted from plants are prodrugs, and thus first become active following metabolic transformation, it means that experimentation and evaluation of results are particularly difficult in this context.

## Introduction

The therapeutic outcome of a drug is influenced by several factors, including the pharmacokinetic and pharmacodynamic profile of the agent in animals and humans. In order for a drug to produce a pharmacological effect, it must come into contact and interact

with a biological system. Consequently, after administration of a drug, it undergoes absorption, distribution, metabolism, and excretion (ADME) in the body. Although absorption is bypassed when a drug is administered intravenously, distribution and elimination of all drugs must occur in the body irrespective of the route of administration. The quantitative study of the kinetics of drug absorption, distribution, and elimination is known as pharmacokinetics. The related discipline of pharmacodynamics evaluates the relationship between the concentration of the drug at the site of action and the pharmacological effect. Increasingly, pharmacokinetic and pharmacodynamic principles are used to relate the concentration of a drug in plasma to the pharmacological response in order to establish the time

course of the drug effect. An understanding of the ADME and pharmacodynamics is essential for a rationale approach to drug discovery and development, and optimization of dosage forms in the clinical setting. In this article, the relevance of ADME in drug discovery and clinical practice is discussed. The application of the open one-compartment pharmacokinetic model to simplify our understanding of the plasma concentration–time profile and current *in vitro* approaches used to study the ADME of drugs are also highlighted.

## Importance of ADME

Successful drug candidates must have the right ADME profiles in addition to desirable pharmacological and toxicological profiles *in vitro* and *in vivo*. Unfavorable ADME profiles contribute significantly to the failure rates of drug candidates during drug discovery. Additionally, ADME studies provide supportive information to facilitate the interpretation of pharmacology and toxicology findings during drug discovery. As a result, pharmaceutical companies are allocating a considerable amount of resources for the evaluation of the ADME of drug candidates in the early stages in order to find the right ADME balance and reduce the failure rates of drug candidates in the later stages of drug discovery. ADME studies allow the identification of drugs that would be absorbed after administration but are also eliminated at acceptable rates, so that a desirable steady-state plasma concentration is attained in a target population when a suitable dosage regimen is given. Furthermore, regulatory authorities are demanding information on ADME profiles and biological activity before new drug applications are approved. Although ADME studies are routinely performed *in vitro* and in animals, increasingly these types of investigations are conducted in humans as well, and the information that is generated is critical in all phases of drug discovery and development programs. Clearly, a full consideration of the factors that influence the plasma concentration–time profiles of drugs *in vivo* is pivotal in the discovery and use of drugs.

## Routes of Drug Administration

Several routes of drug administration, including extravascular (oral, intramuscular, subcutaneous, transdermal, inhalation, etc.) and intravascular routes (intravenous and intra-arterial), are used to deliver drugs into the body. Oral administration of drugs is the most common route because it is

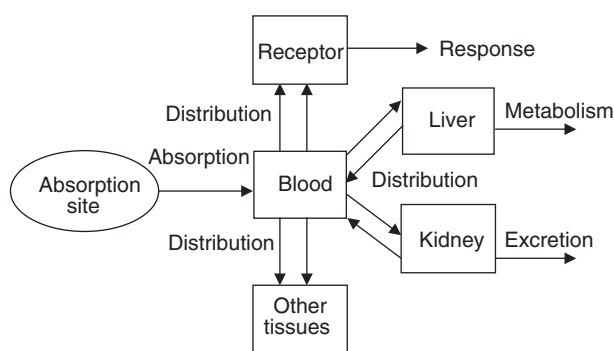

relatively convenient and safe. Many factors – including the physicochemical properties of drugs, type of formulation, physiology of the gastrointestinal tract (GIT), other drugs, and food – affect the way in which drugs are absorbed after oral administration. Although drug absorption occurs in the mouth and stomach, it takes place mostly in the small intestine due to the large surface area. After oral administration, the drug must pass through the intestinal wall and liver in order to reach the general circulation. The drug metabolism enzymes in the intestinal wall and liver metabolize many drugs, thereby decreasing the amount of drug that is bioavailable. This phenomenon is often referred to as first-pass metabolism. The acidic environment and digestive enzymes in the stomach may also chemically degrade some drugs, resulting in erratic absorption. In contrast, drugs administered intravenously do not undergo absorption and therefore the entire dose reaches the general circulation intact.

## Fate of Drugs in the Body

When a drug is administered to a human or an animal, a sequence of events must occur in order for the drug to be effective; the drug must be liberated from the dosage form and dissolved in the fluids at the site of absorption. Several factors influence the rate and extent of dissolution of the drug at the site of absorption, including the solubility of the drug, particle size, and surface area of a solid dosage form. The transfer of the unchanged drug molecules from the site of absorption into the systemic circulation is referred to as absorption. The drug molecules that arrive in the general circulation are reversibly transferred between the blood and other tissues (distribution). At the same time, the drug is eliminated from the body by excretory organs such as the kidney (excretion) or by metabolism to metabolites that are readily excreted. At the site of action, drug molecules interact with receptors to initiate a cascade of events that elicit a pharmacological response (pharmacodynamics). In essence, after entering the body, the drug acts on the body to produce a response, and simultaneously the body acts on the drug to remove it from the system (Figure 1). The processes of ADME directly impact the plasma concentration–time profile of a drug and ultimately its pharmacodynamic effects.

## Absorption

After extravascular administration, a drug must be transferred from the site of absorption, through a cell

**Figure 1** Schematic representation of the fate of a drug in the body.

membrane, in order to enter the systemic circulation. The physicochemical properties of the drug and the structure of the cell membrane influence the passage of the drug from the site of administration into the general circulation. Although there is considerable variation in the structure and function of biological membranes, the basic structure of the cell membrane is a bimolecular lipid layer, which is associated with proteins and small aqueous pores. The transport of drugs across cell membranes is mediated by several mechanisms, including passive diffusion, facilitated transport, active transport, endocytosis, exocytosis, and ion-pair transport. Accumulated evidence indicates that passive diffusion is the most common mechanism of drug absorption. Passive diffusion is driven by lipid solubility and the magnitude of the drug concentration gradient across the cell membrane and governed by Fick's first law according to eqn [1]:

$$\text{flux} = -DA \frac{\Delta C}{h} \quad [1]$$

The flux refers to the flow of drug molecules across an area ( $A$ ) per unit time;  $\Delta C/h$  is the concentration gradient divided by the membrane thickness ( $h$ ), and  $D$  is the diffusion coefficient of the drug. The negative sign indicates that drug transfer occurs from an area of high concentration to one of low concentration. In general, the membrane lipid bilayer is highly permeable to lipid-soluble drugs and poorly permeable to water-soluble drugs. However, some embedded proteins in membranes can form channels, carriers, or pumps that facilitate the movement of polar drugs across membranes. The rate of diffusion of a drug also depends on its molecular size, although the variation with molecular weight is modest for drugs with molecular weights of 200–1000 Da. The degree of ionization of a drug also plays a significant role in the diffusion of the drug across membranes. Since most drugs are either weak acids or bases, their

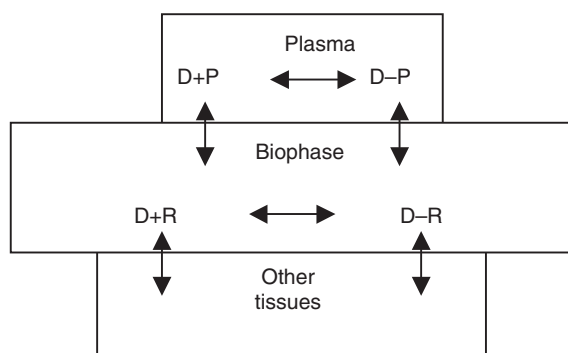

**Table 1** Ionization constants ( $pK_a$ ) of some drugs

<i>Weak bases</i>		<i>Weak acids</i>	
<i>Drug</i>	$pK_a$	<i>Drug</i>	$pK_a$
Chloroquine	10.7	Levodopa	2.2
Amphetamine	9.8	Penicillins	2.5–2.7
Orphenadrine	8.4	Aspirin	3.5
5-Fluorouracil	8.1	Ibuprofen	4.4
Codeine	6.0	Warfarin	5.0
Aminopyrine	5.0	Chlorothiazide	6.8
Diazepam	3.3	Phenobarbital	8.1
Caffeine	0.8	Phenytoin	8.3

degree of ionization will influence their ability to cross biological membranes. The proportion of the drug present in either the ionized or nonionized form depends on the ionization constant,  $pK_a$ , and pH at the absorption site. The  $pK_a$  values of some drugs are given in Table 1. Acidic drugs are predominantly in the nonionized form when the pH value of the environment in which they are present is below their  $pK_a$  values, while basic compounds are predominantly unionized when the pH value of the environment in which they are present is above their  $pK_a$  value. For many drugs, the ionized species exhibits low lipid solubility and poor membrane permeability except when specific carrier mechanisms are in operation. Conversely, the unionized species of most drugs are lipid soluble and readily cross biological membranes. For example, a weak acid such as aspirin will be concentrated in plasma (pH 7.4) with respect to the gastric juice (pH 3.0) because the pH of the stomach favors its absorption. However, it is important to note that the large surface area of the ileum compared to the stomach plays a far more significant role than the pH partition in drug absorption. The factors that influence drug absorption have a significant impact on the overall pharmacokinetics of the drug in question.

## Distribution

After a drug is absorbed into the systemic circulation, it mixes rapidly in the blood and is transferred reversibly into the various tissues and site of action in the body. The rate and extent of distribution of drugs into different tissues depends on their physicochemical properties such as ability to cross cell membranes, affinity of drugs to certain tissues, pH partition, and fat/water partition. In each of the body compartments, drugs exist in both free and bound form (Figure 2). Many acidic drugs that are tightly bound to plasma proteins such as albumin reside

**Figure 2** Schematic representation of drug (D) binding to plasma proteins (P) and receptors (R) in body compartments.

mainly in the bloodstream. For many drugs, it is the free form that is pharmacologically active, because it can readily cross capillary membranes. Therefore, changes in drug binding due to drug–drug interactions or disease conditions may cause significant changes in redistribution and pharmacological effect of a drug in the body. Several drugs do not exhibit a uniform pattern of distribution in the body. For example, thiopental tends to accumulate in body fat, chloroquine concentrates in melanin-containing tissues such as the liver, while small polar drugs are distributed in total body water. Physiologic factors such as blood flow to the tissues also influence the distribution of drugs in the body. Since lipophilic drugs cross cell membranes more readily than hydrophilic ones, their distribution in highly perfused tissues is often significant. Conversely, accumulation of drugs in adipose tissue is limited by its blood flow, which is less than 2% of the cardiac output. The pattern of distribution of a given drug in different body compartments may have important implications on its pharmacokinetics and pharmacodynamics in humans and animals.

## Elimination

Drugs are irreversibly eliminated from the body mainly by the processes of renal excretion and hepatic metabolism. Drugs may also be excreted from the body via the bile, feces, lungs, sweat, and breast milk. Excretion refers to the processes by which the body removes the unchanged drugs and their metabolites through the organs of excretion such as the kidneys. Through the processes of filtration, tubular reabsorption, and secretion, the kidneys remove mostly water-soluble drugs and their metabolites from the blood and excrete them into the urine. Several factors – including plasma protein binding, urinary pH, the dissociation constant ( $pK_a$ ) of the

drug, urine flow, and renal blood flow – can affect the efficiency of the kidneys to excrete drugs and metabolites. For example, drugs that are tightly bound to plasma proteins are not readily filtered by the glomerulus. At low glomerular filtrate pH, weak acidic drugs are unionized and reabsorbed in the tubules of the nephron, whereas at high pH they are ionized in the filtrate and excreted into the urine. The efficiency of the kidney in excreting drugs may be impaired by several factors, including age and diseases states, such as high blood pressure and diabetes. In such cases, the drug dosage may be adjusted especially if the drug is eliminated primarily by the kidneys.

Drug metabolism or biotransformation is the process by which a drug is chemically altered by enzymes in the body to produce a metabolite. Although biotransformation can occur in several organs, the liver is the principal organ of drug metabolism. The cytochrome P450 family of enzymes in the liver mediate phase I biotransformation reactions such as oxidation, reduction, hydroxylation, and hydrolysis of drugs. The cytochrome P450 has broad substrate specificity, and the structural features of a particular drug may help to predict potential metabolic pathways. Cytochrome P450 3A (CYP3A) is estimated to metabolize 50–70% of drugs that are in current use. For example, it has been demonstrated that lopinavir, a protease inhibitor, produces inadequate therapeutic concentrations, when administered alone, due to extensive metabolism by CYP3A isoenzymes. Phase II biotransformations such as glucuronidation, sulfation, acetylation, and glycine conjugation are carried out by transferases that attach endogenous macromolecules to drugs or their metabolites to produce highly polar metabolites. Ezetimibe, a lipid-lowering drug, is extensively conjugated to ezetimibe-glucuronide, a pharmacologically active metabolite. In addition, some drugs and metabolites are excreted into the bile. For most drugs, phase II metabolism must occur before excretion into the bile. The drugs and metabolites in the bile are dumped into the GIT and excreted in the feces. Interestingly, drugs and metabolites in the bile that enter the GIT are available for reabsorption into the bloodstream if they escape decomposition and excretion. This phenomenon is referred to as enterohepatic cycling.

A number of factors such as age, sex, fasting, disease, genetics, and pregnancy influence the metabolism of drugs. For example, drug metabolism capacity is lower in infants because metabolic enzyme systems are only partially developed at birth. Other factors such as physicochemical properties and physiologic variables affect drug metabolism. For example, lipid-soluble compounds are primarily

metabolized in the liver. Moreover, the binding characteristics of drugs also affect their intrinsic metabolic clearance. Extensive plasma protein binding tends to retard hepatic metabolism since bound drugs generally do not have access to metabolic sites, such as hepatocytes in the liver. Although drug metabolism is essentially a deactivation process, it is important to note that metabolites may possess similar or different degrees of pharmacological or toxicological activity as the parent drug. Prodrugs, for example, produce the desired therapeutic effects after biotransformation of an inactive form of a chemical entity to active metabolites in the body.

Several *in vitro* systems and animal models are available to evaluate metabolic stability of drugs, identify the enzyme systems that are involved in their metabolism, and predict drug–drug interactions. The Michaelis–Menten expression (eqn [2]) is commonly used to describe the relationship between the rate of metabolism ( $V$ ) and the concentration of the substrate ( $C$ ). This equation is a fundamental interpretation of how an enzyme interacts with a drug, where  $K_m$  is defined as the substrate concentration at half the maximum rate of metabolism ( $V_{max}$ ). Interestingly, the rates of metabolism obtained from human *in vitro* systems such as liver microsomes may be used to predict drug hepatic clearance in humans when the drug concentrations are low relative to  $K_m$ . The *in vitro* intrinsic clearance ( $CL_{int}$ ), a measure of the innate enzyme activity to metabolize a drug, is determined from the ratio of  $V_{max}$  to  $K_m$  of the major metabolic pathways and forms the basis for the prediction of *in vivo* hepatic clearance. Using this method, the intrinsic clearance obtained from human liver microsomal experiments is scaled up to *in vivo* hepatic clearance using appropriate scaling factors such as microsomal protein content, protein binding, liver weight, and blood flow. This approach has been demonstrated to provide good predictions of hepatic clearance in intact animals and humans:

$$V = \frac{V_{max}C}{K_m + C} \quad [2]$$

## Drug Transporters

In recent years, it has become apparent that transport proteins play a major role in regulating the absorption, distribution, and excretion of several drugs. Briefly, accumulated evidence has demonstrated that P-glycoprotein (P-gp), a transporter that is embedded in several biological membranes including the blood–brain barrier (BBB) and the GIT, plays an important role in the ADME of many drugs. A major function of P-gp is the energy-dependent cellular efflux of

endogenous substrates and the excretion of drugs and metabolites into urine, bile, and the intestinal lumen. Some studies have shown that digoxin, a P-gp substrate, has significantly higher bioavailability in subjects with reduced P-gp function. At the BBB, P-gp limits the accumulation of many drugs – including digoxin, vinblastine, dexamethasone, and cyclosporine – in the brain. Although P-gp transports a wide range of substances with diverse chemical structures, lipophilic and amphipathic drugs appear to be particularly good P-gp substrates. Interestingly, P-gp and cytochrome P450 3A4 (CYP3A4) are both localized in tissues with major function for drug absorption and disposition, such as the small intestine and liver; it also appears that the substrate specificities of P-gp and CYP3A4 show significant overlap. This observation is of particular importance because P-gp and CYP3A4 may work in a coordinate fashion to influence drug absorption and disposition in the body. The role of drug transporters in modulating drug absorption, distribution, and excretion may contribute to variability in drug pharmacokinetics and pharmacodynamics.

## Plasma Concentration–Time Profile

A plot of the concentration of the drug in plasma against time is referred to as the plasma concentration–time profile. The processes of ADME influence the concentrations of drugs in blood with respect to time. For drugs that are rapidly distributed in the body, changes in the concentrations of the drug in blood reflect changes in the concentration of the drug in other tissues. In order to achieve a desirable therapeutic effect, the drug concentrations in the blood are maintained within a desirable concentration range (Figure 3). This is especially true when the drug concentration in plasma is rapidly equilibrated with the site of action. However, the relationship

**Figure 3** Plasma concentration–time curve after intravenous (IV) and oral (PO) administration of a single dose of a hypothetical drug showing the therapeutic range, minimum effective concentration (MEC), and minimum toxic concentration (MTC).

between drug concentration in plasma and therapeutic effect has not been delineated for many drugs.

## Pharmacokinetic Models

Various pharmacokinetic models are commonly used for the quantitative description of the plasma concentration–time profile. In spite of the inherent assumptions and limitations of these models, they are useful in predicting drug concentration in plasma, urine, and other tissues at different times after drug administration. Pharmacokinetic models are also used to design the optimum dosage regimen, estimate tissue accumulation of drugs and their metabolites, and explain drug–drug interactions and effects of disease on the ADME of drugs in the body. In this article, the open one-compartment models will be highlighted to illustrate how the main pharmacokinetic parameters are determined from a set of drug concentrations in plasma versus time data.

### One-Compartment Model – Instantaneous Input

After intravenous administration of a single bolus dose of a drug that is rapidly distributed in the body, it bypasses the process of absorption and may be removed from the body by a single first-order elimination pathway (Figure 4). The equation that describes the rate of change of drug concentrations in plasma ( $dC_p/dt$ ) for a drug that is rapidly distributed in the body after intravenous administration and follows first-order elimination is shown in eqn [3]. The corresponding integrated form of eqn [3] that describes the concentration of the drug in plasma ( $C_p$ ) at any time ( $t$ ) is depicted in eqn [4]. In this case, the elimination rate constant ( $k_{el}$ ) controls the amount of the drug eliminated per unit time. The pharmacokinetic parameters such as  $k_{el}$ , elimination half-life ( $t_{1/2}$ ), volume of distribution ( $V_d$ ), and clearance (CL) that are determined from the blood concentration–time profile of a drug are useful in drug discovery and for the design of suitable dosage regimens.

$$\frac{dC_p}{dt} = -k_{el}C_p \quad [3]$$

$$C_p = C_0 e^{-k_{el}t} \quad [4]$$

**Figure 4** Schematic representation of the one-compartment model showing drug input, a single first-order elimination step, and associated pharmacokinetic parameters.

### Elimination Half-Life

The elimination half-life ( $t_{1/2}$ ) is the time required for the amount of drug in the body to decrease by half (eqn [5]). The half-life is independent of the dose of the drug administered and is a useful indicator of how fast a drug is removed from the body. It takes five elimination half-lives for  $\sim 97\%$  of the bioavailable dose to be eliminated from the body. The half-life is useful to estimate the dosing interval, the duration of action of a drug, and the time required to attain steady-state plasma concentrations during a multiple dosage regimen. The volume of distribution and clearance of a drug influence the half-life (eqn [6]). For example, the antimalarial drug chloroquine has a high clearance but a very long half-life due to its large volume of distribution. In some renal and hepatic diseases, the half-life may remain unchanged although the clearance and volume of distribution may change by the same proportion. In such situations, the half-life is not a good indicator of drug elimination from the body:

$$t_{1/2} = \frac{0.693}{k_{el}} \quad [5]$$

$$t_{1/2} = \frac{0.693 V_d}{CL} \quad [6]$$

### Volume of Distribution

The apparent volume of distribution ( $V_d$ ) is a virtual volume required to relate the plasma or blood concentration ( $C_p$ ) to the amount ( $A_p$ ) of a drug in the body. In fact,  $V_d$  is the proportionality constant when the plasma or blood concentration of a drug is proportional to the amount of drug in the body. The amount of drug in the body at zero time after administration of a single intravenous dose is equivalent to the dose ( $D$ ). In this case, knowledge of the initial drug concentration in plasma ( $C_0$ ) provides a simple approach for estimating the  $V_d$  of a drug that distributes rapidly in a single homogeneous compartment:

$$V_d = \frac{D}{C_0} \quad [7]$$

$V_d$  is an important pharmacokinetic parameter that is used to calculate the priming dose of a drug that will achieve a required steady-state plasma concentration. In addition, it is a useful indicator of the extent of drug distribution from the blood to the tissues. Drugs that are highly bound to plasma proteins reside mainly in blood, resulting in a high blood concentration and a  $V_d$  that is approximately the volume of blood (5 l) in the average adult human.

**Table 2** Apparent volume of distribution for some drugs in humans

Drug	$V$ (l, 70 kg)
Heparin	5
Sulfisoxazole	11.2
Phenobarbital	38.5
Ethosuximide	49
Diazepam	168
Digoxin	490
Haloperidol	1400
Chloroquine	12 950

On the other hand, drugs that are extensively distributed in the body exhibit a large apparent  $V_d$ . In this case, the apparent  $V_d$  is likely to be greater than the true body volume. In general, the apparent  $V_d$  for drugs ranges from the plasma volume to values that are much larger than the body volume (Table 2).

### Clearance

The total body clearance (CL) is an important pharmacokinetic parameter that measures the efficiency with which a drug is irreversibly removed from the body by all organs of elimination. Thus, the sum of the clearance values of individual organs of elimination is equal to the systemic clearance. For most drugs, the systemic clearance of a drug is influenced by the capacity of the liver to metabolize the drug and the inherent ability of the kidney to excrete the unchanged drug. The total clearance, defined as the volume of blood cleared of the drug per unit time, can be calculated from the intravenous bolus dose ( $D$ ) and the area under the plasma concentration–time profile extrapolated to infinity ( $AUC_{(0 \rightarrow \infty)}$ ) as shown in eqn [8]:

$$CL = \frac{D}{AUC_{(0 \rightarrow \infty)}} \quad [8]$$

The total clearance is also a function of blood flow to specific organs of elimination and the extraction ratio. The extraction ratio is an empirical measure of the efficiency of an eliminating organ. Thus, disease states that affect the condition of organs of elimination may alter blood flow, extraction ratio, and ultimately the systemic clearance of drugs.

### Bioavailability

Several factors – including the route of administration, the physicochemical properties, dosage form, and the physiological state of an individual – can affect the amount of the administered dose of a drug that reaches the systemic circulation after extravascular administration. The term bioavailability ( $F$ )

**Figure 5** Nifedipine concentrations in plasma after a single intravenous dose of 25 mg to a patient. The data show a mono-exponential decline with a  $t_{1/2}$  of 2.2 h and elevated concentrations of the drug in plasma when elimination rate is reduced ( $t_{1/2} = 4.8$  h).

refers to the rate and extent to which a drug is absorbed into the bloodstream. The fraction of the administered dose that reaches the systemic circulation after administration by any extravascular route is often calculated from the ratio of the area under the plasma concentration–time profile extrapolated to infinity ( $AUC_{(ext)}$ ) after extravascular administration to the area under the plasma concentration–time profile extrapolated to infinity ( $AUC_{(iv)}$ ) after intravenous administration of the same dose as shown in eqn [9]:

$$F = \frac{AUC_{(ext)}}{AUC_{(iv)}} \quad [9]$$

The area under the plasma concentration–time curve is a useful indicator of the amount of drug that reaches the systemic circulation and of the duration resides there before it is removed. The processes of ADME influence the plasma concentration–time profile of an administered drug and the associated parameters. For example, a reduction in the rate of elimination of nifedipine will result in elevated and prolonged drug levels in plasma (Figure 5).

### New Technologies for Studying ADME

The introduction of new technologies in recent years is increasing the throughput of ADME studies during the drug discovery process. The advent of cell culture techniques in recent years has facilitated the assessment of intestinal permeability for many drugs. A notable example is the use of CaCO-2 cells, an immortalized human colon adenocarcinoma cell line

that contains microvilli, expresses functional transport proteins and metabolic enzymes, and retains many characteristics of the intestinal brush border to predict oral bioavailability of drugs based on the capacity of the drugs to cross the CaCO-2 cell monolayer. Although it has been demonstrated that bioavailability can be predicted with reasonable accuracy using this model for some drugs, *in vitro* approaches are still inferior to animal studies.

In drug discovery, several *in vitro* and animal models are available to evaluate drug distribution. For example, the bovine brain micro-endothelial capillary model (BBMEC), cultured from blood vessels of the BBB, can be used to predict the transport of drugs across the BBB. Plasma protein binding studies, readily performed using standard techniques, augment our understanding of the relationship between total plasma drug concentrations and the unbound drug concentration that is available to interact with the receptors. Traditional *in vivo* techniques such as whole-body autoradiography are also still used to characterize drug distribution in animals and humans.

Several *in vitro* methods such as microsomes and recombinant enzymes are available for evaluating drug metabolism. The high volume of information gathered from *in vitro* drug metabolism studies is useful in choosing drug candidates for future development and for predicting *in vivo* intrinsic clearance of drugs. Although some insight into the various aspects of ADME can be obtained from *in vitro* methods, there are no robust alternatives to intact animals to predict accurately the pharmacokinetic profiles of drug candidates after administration to a whole animal or person at the present time. However, the prediction of *in vivo* pharmacokinetics from *in vitro* data will continue to improve as our understanding of the roles of transporters and cytochrome P450 enzymes in ADME increases. Furthermore,

the advent of *in silico* approaches to predict ADME profiles of drugs based on chemical structure, physicochemical properties, crystal structure of biotransformation enzymes, and ADME profiles of a library of known drugs will increase the efficiency of predicting ADME properties and ultimately the plasma concentration–time profiles of drugs in the body.

## Introduction

The fate of a drug in the body involves the processes of absorption, distribution, metabolism, and excretion (ADME), which control the time course of a drug *in vivo* and the interaction of a drug with

receptors in order to produce a biologic effect (Figure 1). While pharmacokinetics examines how the body handles a drug after administration, pharmacodynamics deals with the relationship between the concentrations of a drug at the site of action and the response elicited, including the mechanisms of interaction between a drug and receptors in the body. The interaction of a drug with specific receptors or enzymes initiates a cascade of molecular events that trigger a pharmacodynamic response. In many cases,

that contains microvilli, expresses functional transport proteins and metabolic enzymes, and retains many characteristics of the intestinal brush border to predict oral bioavailability of drugs based on the capacity of the drugs to cross the CaCO-2 cell monolayer. Although it has been demonstrated that bioavailability can be predicted with reasonable accuracy using this model for some drugs, *in vitro* approaches are still inferior to animal studies.

In drug discovery, several *in vitro* and animal models are available to evaluate drug distribution. For example, the bovine brain micro-endothelial capillary model (BBMEC), cultured from blood vessels of the BBB, can be used to predict the transport of drugs across the BBB. ## Introduction

The fate of a drug in the body involves the processes of absorption, distribution, metabolism, and excretion (ADME), which control the time course of a drug *in vivo* and the interaction of a drug with

receptors in order to produce a biologic effect (Figure 1). While pharmacokinetics examines how the body handles a drug after administration, pharmacodynamics deals with the relationship between the concentrations of a drug at the site of action and the response elicited, including the mechanisms of interaction between a drug and receptors in the body. The interaction of a drug with specific receptors or enzymes initiates a cascade of molecular events that trigger a pharmacodynamic response. In many cases,

**Figure 1** Schematic representation of the time course of drug action and the relationship between pharmacokinetics and pharmacodynamics.

the effect produced by a drug is correlated to the concentration of the drug at the site of action. Consequently, factors that influence the circulating concentration–time profile of a particular drug are expected to influence the onset, duration, and intensity of the pharmacodynamic effect. During drug discovery and development, pharmacodynamic studies provide an understanding of the mechanism of action of a drug and other critical information that are used for the selection of drug candidates. In addition, the information generated in pharmacodynamic investigations is useful for optimizing drug therapy in the clinical setting. In this article, the basic principles of pharmacodynamics and the models that are used to characterize the drug concentration–effect relationships are discussed. The application of the pharmacokinetic–pharmacodynamic link modeling to increase our understanding of the time course of drug effects is also highlighted.

## Basic Principles of Drug Action

It has been widely demonstrated that drugs interact with specific classes of receptors or interfere with specific signaling pathways in order to induce a pharmacodynamic effect. Receptors denote macromolecules with which a drug interacts in order to initiate biochemical and physiological changes in an organism. Several classes of drug receptors, including receptors for androgens (**Figure 2**) and other endogenous hormones, have been described. Incidentally, many drugs with specific chemical structures also selectively interact with receptors for endogenous ligands. Drug–receptor interactions may involve ionic, hydrogen, van der Waals, and covalent bonding. Generally, many drugs rapidly interact with free receptors in a reversible fashion, and the resulting drug–receptor complex triggers a rapid and direct

**Figure 2** Conversion of testosterone (T) to dihydrotestosterone (DHT) by 5 $\alpha$ -reductase (5 $\alpha$ R), interaction of DHT with the androgen receptor (AR), and binding of the DHT–AR complex to the androgen response elements (ARE) in the androgen signaling pathway.

response as shown schematically below:

The scheme illustrates that the drug, receptor, and drug–receptor complex are at equilibrium and assumes that a single drug molecule interacts with a single receptor site. The law of mass action is commonly used to describe the interaction of a drug molecule with a receptor site. According to this approach, the rate of production of a pharmacodynamic effect is proportional to the molar concentrations of the drug at the receptor site [Drug] and the concentration of the receptor [Receptor] in the same way that the rate of an enzyme reaction is proportional to the molar concentrations of the substrate and the enzyme. A greater pharmacological effect is produced, as the drug molecules occupy more receptors, until a maximal effect is attained. The receptor occupancy theory considers a drug that binds to a receptor, mimics the effects of the endogenous ligand, and produces a maximal response as a full agonist; a drug that binds to a receptor and elicits less than a

maximal response is referred to as a partial agonist. Inverse agonists constitute another category of ligands, which produce an effect opposite to that of the agonist by occupying the same receptors. The term antagonist is used to describe a drug that binds to the receptor but does not activate it. Therefore, antagonists do not produce a response because they lack intrinsic activity. Antagonists also interfere with the interaction of an agonist with the receptor. For example, flutamide, a drug that is used to treat prostate cancer, works by blocking the androgen receptors on the surface of the prostate cancer cells and prevents the interaction of the natural ligands, testosterone or its derivative, dihydrotestosterone (DHT), with the androgen receptors (Figure 2). Incidentally, DHT binds to the androgen receptor with about five times greater affinity than testosterone. Since most prostate cancers depend on the supplies of these hormones to grow, flutamide interferes with the action of these androgens and retards or stops the proliferation of prostate cancer cells. Flutamide interacts with the androgen receptor in a specific manner since it has a structure similar to testosterone.

Drugs that bind to the same receptors are also differentiated in terms of efficacy and potency. The intrinsic ability of a drug to produce a specific response is referred to as efficacy. If the relationship between the concentration of a drug and the response is described by a simple hyperbolic profile, the height of any point on the concentration–effect curve that represents a desired response is a measure of the efficacy of a drug (Figure 3). In contrast, potency is a measure of the concentration of a drug needed to elicit a specific response. The width of a point from left to right of the concentration–effect curve is a measure of potency (Figure 3). Therefore, agonists that produce the same pharmacodynamic effect may

**Figure 3** Hyperbolic relationship between the drug concentration and pharmacodynamic effect.  $E_{\max}$  is the maximal effect and  $EC_{50}$  is the drug concentration required to produce 50% of the maximal effect.

exhibit different efficacy and potency. The relationship between the concentrations of epinephrine and norepinephrine, catecholamines with  $\alpha$ - and  $\beta$ -adrenergic receptor activity, and increase in blood pressure are described by graded concentration–effect curves as shown in Figure 4. Epinephrine and norepinephrine interact with the same receptors and produce the same maximal effect, indicating that they are equally effective and may be described as full agonists. Additionally, epinephrine and norepinephrine activate the same number of receptors since efficacy is proportional to the number of receptors activated. However, the concentration of drug required to activate a similar number of receptors is not the same for the two agonists. The concentration of each drug, which produces a half-maximal response, is useful for comparing drugs that act on the same receptors. The potency of epinephrine is greater than that of norepinephrine since the concentration required to produce a half-maximal response is lower. Although epinephrine and norepinephrine are equally effective in eliciting a maximal increase in blood pressure, ephedrine produces a submaximal increase in blood pressure (Figure 4). Thus, ephedrine activates fewer receptors than epinephrine or norepinephrine and is described as a partial agonist.

The enzymes of important signaling pathways are also exploited as drug targets. Inhibitors of enzymes are useful as drugs by selectively blocking specific metabolic pathways, decreasing the concentration of metabolic products or increasing the concentration of enzymatic substrates. In fact, about half of the top

**Figure 4** Sigmoidal relationship between the logarithm of drug concentration ( $\log C$ ) and pharmacodynamic effect.  $E_{\max}$  is the maximal effect and  $EC_{50}$  is the drug concentration to give 50% of the maximal effect. Drugs A (e.g., epinephrine) and B (e.g., norepinephrine) are full agonists and have the same efficacy ( $E_{\max}$  of drug A is the same as  $E_{\max}$  of drug B), but the potency of drug A is higher than that of drug B ( $EC_{50}$  of drug A is lower than  $EC_{50}$  of drug B). Drug C (e.g., ephedrine) is a partial agonist and less potent.

20 drugs sold worldwide are enzyme inhibitors. For example, the aromatase inhibitors such as letrozole and anastrozole reduce the synthesis of estrogens by inhibition of the aromatase enzyme system, which catalyzes the rate-limiting step in the biosynthesis of estrogens from androgenic precursors. Several aromatase inhibitors have been developed in the last few years for breast cancer treatment: the new aromatase inhibitors are considerably more selective, highly potent, and effective in decreasing circulating estrogen concentrations. For example, the efficacy of letrozole for aromatase inhibition has been reported to be greater than 98% at the  $0.5 \text{ mg day}^{-1}$  dose in breast cancer patients.

## Structure–Activity Relationships

The connection between the chemical structure of a drug and its intrinsic activity has been well established. In fact, the molecular structure of a drug influences the nature of drug–receptor interaction and the response that is produced. In drug discovery, the chemical structure of new chemical entities is usually exploited in designing new drugs. Traditionally, new chemical entities are synthesized, tested for pharmacological activity, and structure–activity trends established. Increasingly, mathematical models are used to predict structure–activity relationships. In this case, physicochemical properties such as lipophilicity, electronics, and sterics are used to predict biological activity of potential new drugs. Some therapeutically useful inhibitors of androgen signaling, for instance, have been developed by chemical modification of the chemical structure of the endogenous substrates. The design of steroidal inhibitors of  $17\alpha$ -hydroxylase/ $C_{17,20}$ -lyase, a key enzyme in the biosynthesis of androgens that converts the  $C_{21}$  steroid precursors (pregnenolone and progesterone) to the corresponding  $C_{19}$  androgens, dehydroepiandrosterone, 5-androstenediol, testosterone, and androstenedione, is based on the chemical modification of the endogenous ligands. The anabolic steroid stanozolol has been shown to be a potent competitive inhibitor of  $17\alpha$ -hydroxylase/ $C_{17,20}$ -lyase. Various structural modifications of new chemical entities have been shown to have identifiable effects on drug–receptor interaction, ADME properties, and ultimately on the pharmacodynamic activity of the agent.

## Concentration–Effect Relationships

An important consideration of pharmacodynamics is the concentration–effect relationship, which allows one to evaluate how much a response changes when

the drug concentration is increased. The concentration–effect relationship also allows us to determine the potency and efficacy of a drug in order to compare its effects with that of other agonists producing the same response and to determine the safety margin of the drug. It has been demonstrated on several occasions that the drug effect is better correlated to the circulating drug concentration than the administered dose. Therefore, the drug concentration–effect relationship must be properly characterized for optimal drug therapy. The drug concentration at the receptor site depends on the dose; typically the drug concentrations increase as the dose is increased. For most drugs, as the concentration at the receptor site increases, the pharmacological effect increases in a hyperbolic manner, approaching a plateau (Figure 3). Although several mathematical approaches have been used to evaluate the concentration–effect relationship, the Hill expression (eqn [1]) is commonly used to describe the relationship between the concentration of the drug at the site of action ( $C$ ) and the pharmacodynamic effect ( $E$ ). This equation is a basic interpretation of how a drug interacts with a receptor; the affinity of the drug for the receptor is described by  $EC_{50}$ , the concentration of the drug required to produce 50% of the maximal effect ( $E_{\max}$ ). The Hill coefficient ( $s$ ), the number of drug molecules that combine with each receptor molecule, influences the slope and shape of the concentration–effect curve:

$$E = \frac{E_{\max} C^s}{EC_{50}^s + C^s} \quad [1]$$

According to the Hill equation, the maximal effect is attained when the receptor is saturated with the drug. When the effect is plotted against the logarithm of concentration, the concentration–effect curve becomes sigmoidal in shape and shows an approximately linear range between 20% and 80% of the maximal effect (Figure 4). An approximately log-linear relationship between 20% and 80% of the maximal effect is commonly observed for most drugs used at therapeutic doses. Above 80% of the maximal effect, very little increase in response occurs by a given increase in drug concentration, but the risk of adverse effects increases. In addition, some studies have defined the therapeutic range for some drugs: the plasma concentration range that is safe and effective in treating specific diseases in patients. The desired therapeutic effects of a drug are seen within the therapeutic range; subtherapeutic effects are seen below the therapeutic range, and above the therapeutic range there is a greater probability that toxicity may occur.

**Figure 5** Illustration of competitive and noncompetitive antagonism. Competitive antagonism shifts the concentration–effect curve of an agonist to the right without altering the  $E_{\max}$ . Noncompetitive antagonism lowers the observed  $E_{\max}$  of an agonist. Curve A represents the concentration–effect curve of an agonist by itself. Curve B represents the concentration–effect curve of an agonist in the presence of a competitive antagonist. Curve C represents the concentration–effect curve of an agonist in the presence of a noncompetitive antagonist.

Antagonists are designed to block the responses elicited by endogenous agonists. Although antagonists have no effects by themselves, they affect the concentration–effect curves for agonists. An antagonist may prevent the action of an agonist by competitive or noncompetitive inhibition (Figure 5). In competitive antagonism, the reversible interaction between an antagonist and a receptor can be overcome by increasing the concentration of the agonist. In contrast, increasing the concentration of the agonist does not restore its maximal effect in noncompetitive (irreversible) antagonism. For example, the potency of epinephrine in increasing blood pressure is decreased significantly by prazosin since the receptors occupied by prazosin are not activated by epinephrine.

## Pharmacodynamic Models

Pharmacodynamic models are used to characterize the relationship between the drug concentration and the pharmacological response elicited. The most common pharmacodynamic models that relate the drug concentration at the site of action (or the steady-state drug concentrations in plasma) to a rapid and direct response are based on the Hill equation (vide supra). These models are useful for most drugs that exhibit rapid equilibration between the plasma and receptor compartments, and reversible binding of the drug to the receptors. In this case, there is a predictable relationship between measurable drug

concentrations in plasma and drug concentrations at inaccessible receptor sites. It is the concentration of a drug at the biophase that will ultimately determine the intensity of the pharmacodynamic effect. Pharmacodynamic models that account for irreversible drug–receptor interaction, delayed drug distribution, and production of indirect response are beyond the scope of this article.

### The Maximal Effect Model

The maximal effect ( $E_{\max}$ ) pharmacodynamic model relates drug concentrations and the pharmacodynamic effect ( $E$ ) according to eqn [2]. The  $E_{\max}$  model defines a maximal effect ( $E_{\max}$ ) and shows that a sufficiently large increase in drug concentrations near the  $E_{\max}$  elicits a disproportionately small increase in response. The measured baseline effect ( $E_0$ ) occurs when the drug concentration is zero.  $EC_{50}$  is the concentration of the drug required to produce 50%  $E_{\max}$ . The simple  $E_{\max}$  model has been used to describe the relationship between the concentrations of theophylline in plasma and the bronchodilator activity (forced expiratory volume) in asthma patients. The calculated  $EC_{50}$  and  $E_{\max}$  values for theophylline were  $10 \text{ mg l}^{-1}$  and 63% of normal forced expiratory volume, respectively:

$$E = E_0 + \frac{E_{\max} C}{EC_{50} + C} \quad [2]$$

### The Sigmoidal Maximal Effect Model

The sigmoidal maximal effect ( $E_{\max}$ ) model relates the drug concentration ( $C$ ) and the pharmacodynamic effect ( $E$ ) as depicted in eqn [3]. The sigmoidal  $E_{\max}$  model also defines a maximal effect ( $E_{\max}$ ) and shows that a large increase in drug concentrations near the  $E_{\max}$  produces a disproportionately small increase in response. The sigmoidal  $E_{\max}$  model incorporates a slope factor ( $s$ ) that accounts for differences in the steepness of the concentration–effect relationship. The larger the magnitude of the slope factor, the smaller the change in concentration required to produce a change in response from 20% to 80% of  $E_{\max}$ . The sigmoidal  $E_{\max}$  model reduces to the simple  $E_{\max}$  model when the exponent  $s = 1$ . The simple sigmoidal  $E_{\max}$  model has been used to describe the relationship between the concentrations of propranolol in plasma and the antiarrhythmic effects in patients. The calculated  $EC_{50}$  and  $E_{\max}$  values for propranolol were  $\sim 70 \text{ ng ml}^{-1}$  and 75% success rate, respectively. The  $E_{\max}$  model also accommodates a quantal response when the values of  $s$  are greater than 5. In this case, no pharmacodynamic effect is observed below a certain threshold

concentration and a maximal response is observed at concentrations just above the threshold concentration of the drug:

$$E = E_0 + \frac{E_{\max} C^s}{EC_{50}^s + C^s} \quad [3]$$

### The Log-Linear Model

The log-linear pharmacodynamic model describes the linear relationship between the logarithm of drug concentrations ( $\log C$ ) and the pharmacodynamic response ( $E$ ) between 20% and 80% of the maximal effect as shown in eqn [4], where  $I$  is the intercept of the logarithm of drug concentration versus effect plot and  $m$  is the slope of the regression line. For example, the relationship between the logarithm of the concentration of propranolol in plasma and the antiarrhythmic effects in patients has been shown to be approximately linear between 20% and 80% of the maximal effect:

$$E = m(\log C) + I \quad [4]$$

### The Linear Model

The linear pharmacodynamic model describes a linear relationship between the drug concentration ( $C$ ) and the pharmacodynamic response ( $E$ ) when drug concentrations are significantly below the  $EC_{50}$  as shown in eqn [5].  $E_0$  is the baseline effect when the drug concentration is zero and the ratio of  $E_{\max}$  to  $EC_{50}$  is the slope of the regression line. The simple linear model has been used to describe the relationship between the tissue concentrations of *d*-lysergic acid diethylamide (LSD) and behavioral response (performance scores in arithmetic tests):

$$E = E_0 + \frac{E_{\max}}{EC_{50}} C \quad [5]$$

## Pharmacokinetic–Pharmacodynamic Models

Although the pharmacodynamic effect is primarily a function of the concentration of a drug at the site of action and the affinity of the drug for the receptors, time-dependent processes such as ADME also influence the observed effect. Consequently, the pharmacodynamic effect is also a function of time, especially under *in vivo* conditions where drug molecules may not equilibrate rapidly with the biophase. Recently, relationships between plasma concentrations of drugs and pharmacodynamic effects have received considerable attention. The mathematical analysis of the relationships between pharmacokinetics and pharmacodynamics is often termed

pharmacokinetic–pharmacodynamic (PK–PD) modeling. Although PK–PD models oversimplify drug–receptor interaction, they provide a basis for predicting the time course of drug action and designing dosing regimens. The PK–PD approach is also useful to obtain realistic estimates of the potency and intrinsic activity of the direct effects for drugs exhibiting agonistic properties and the potency of competitive antagonists on the basis of their pharmacodynamic interaction with a full agonist. PK–PD modeling has been applied in studies with many drugs, including benzodiazepines and antiepileptic drugs. Although a detailed description of the various PK–PD models is beyond the scope of this article, we will briefly discuss the time course of a rapid and direct pharmacodynamic effect after a single intravenous dose of a drug that obeys the one-compartment open pharmacokinetic model, and the response is described by the simple  $E_{\max}$  model.

After a single intravenous dose of a drug that obeys the one-compartment open pharmacokinetic model, drug concentrations in plasma fall in a mono-exponential manner with respect to time. Furthermore, a plot of the logarithm of drug concentration in plasma with respect to time is linear. The relationship between the logarithm of drug concentration in plasma and a direct response is also approximately linear within the 20–80% of maximal response range for several therapeutic agents. Therefore, the time course of the pharmacodynamic effect can be established from simultaneous analysis of the plasma concentration versus time and plasma concentration versus effect data obtained after administration of a single intravenous dose of a drug. Using this PK–PD approach, it is apparent that the pharmacodynamic effect falls at a constant rate (zero order) with respect to time in the range of 20–80% of maximal response for drugs that obey the one-compartment model after a single intravenous dose, and the drug effect is described by the simple  $E_{\max}$  model (eqn [6] and Figure 6). The slope of the logarithm of concentration versus effect plot is  $m$  and  $k_{el}$  is the first-order elimination rate constant of the drug;  $E$  is the pharmacodynamic effect at any time ( $t$ ) and  $E_{\max}$  is the maximal response elicited by a single dose. The stimulant effect of amphetamine, for example, declines in a zero-order fashion after administration. If the value of  $m$  or  $k_{el}$  of the drug is very large, the response will decline rapidly after a single intravenous dose. Therefore, a multiple dosage regimen has to be given at small intervals in order to maintain the therapeutic response in such situations. Although the pharmacodynamic effects of many drugs decline at a constant rate after intravenous administration, a first-order decline in response has

**Figure 6** Time course of drug effect after a single intravenous dose of a drug that obeys the one-compartment open pharmacokinetic model, and the response is described by the simple  $E_{\max}$  model.

**Figure 7** Counterclockwise hysteresis of drug concentrations vs. effect.

been observed in some situations:

$$E = E_{\max} - \frac{mk_{el}}{2.3} t \quad [6]$$

#### Duration of Pharmacodynamic Response

Frequently, the duration of action ( $t_d$ ) of a drug is influenced by the amount of drug in the body and the rate of drug elimination. The duration of action may be defined as the time the drug concentration stays within the therapeutic range of a drug. The duration of action for a drug that obeys the one-compartment model after intravenous bolus administration may be calculated using eqn [7], where  $A_0$  is the amount of drug administered;  $A_{\min}$  is the minimum effective dose and  $k_{el}$  is the first-order elimination rate constant of the drug. In this case,  $t_d$  is the time required for the initial amount of drug in the body to decline to the minimum effective amount. This expression demonstrates that there is a linear relationship between the duration of response and the logarithm of the amount of drug in the body. Thus, increasing the dose prolongs  $t_d$  but there is a risk of producing adverse effects if the therapeutic index of the drug is small. Furthermore, the equations show that the duration of action is inversely proportional to the first-order elimination rate constant of the drug. Therefore,  $t_d$  is expected to be prolonged in patients with renal or hepatic failure since impaired efficiency of drug elimination will lead to retention of drug in the body. Notwithstanding, the duration of action is also influenced by pharmacodynamic parameters of a drug in question. Consequently, some drugs such as  $\beta$ -blockers are usually administered once or twice daily, despite having short elimination half-lives, because the doses used are sufficient to produce a maximal effect for a significant part of the dosing

interval:

$$t_d = \frac{2.3}{k_{el}} \left( \log \frac{A_0}{A_{\min}} \right) \quad [7]$$

#### Hysteresis of Response

It has been shown that the drug concentration is not a good indicator of the pharmacodynamic effect in several situations. A looped profile or hysteresis (Figure 7) has been obtained for some drugs when drug concentrations are plotted against response. The loop suggests a time dependency of the response. Additionally, the direction of the loop, which may be clockwise or counterclockwise, may suggest a mechanism for the observed time-dependent response. A clockwise loop may indicate development of tolerance or formation of metabolite with antagonistic effect. In contrast, a counterclockwise loop may indicate slow equilibration of drug concentrations with the receptor site or increased receptor sensitivity. In this case, the response will tend to increase with decreasing concentration of the drug.

In order to obtain a predictive relationship between drug concentrations and pharmacodynamic response, two questions must be addressed: (1) Is drug concentration directly or indirectly related to response? (2) Does the drug interact with the receptors in a reversible or irreversible manner? The quantitative pharmacodynamic approaches described in this article are useful for characterizing rapid and direct responses resulting from reversible drug-receptor interactions. However, drug-receptor interaction initiates a cascade of events, such as formation of second messengers, that ultimately trigger a pharmacodynamic response. These events take time and may affect the time course of drug action *in vivo*. Other

factors, including delayed drug distribution, production of active metabolites, irreversible drug–receptor interactions (for example, the effect of aspirin on cyclooxygenase in platelets), and production of indirect therapeutic effects, complicate the elucidation of the time course of drug effect *in vivo*. In these cases, other appropriate mathematical models are available to establish a good correlation between drug concentration and pharmacodynamic effect and predict the time course of drug action under steady-state conditions *in vivo*. Since the kinetics of a pharmacodynamic effect is influenced by several factors, especially *in vivo*, it is imperative to account for both pharmacokinetic and pharmacodynamic factors when developing realistic PK–PD models with predictive value. The development of robust PK–PD models provides useful information on the nature of the pharmacological properties of drugs and kinetics of drug action *in vivo* both in preclinical and clinical investigations. At the preclinical stage, PK–PD concepts are applicable in the evaluation of *in vivo* potency and intrinsic activity, the identification of suitable markers of therapeutic effect, and optimization of dosage regimens. In the clinical setting, PK–PD concepts are useful in the characterization of the effect versus time relationship and identification of the sources of variability in drug response such as food, age, disease, gender, drug–drug interactions, tolerance development, and genetic polymorphism. Thus, PK–PD concepts provide a promising tool for

selecting new chemical entities for development and optimizing how drugs should be administered.

## Introduction

Pheromones are chemicals that transmit information between individuals of the same species evoking physiological or behavioral responses in the individual receiving the signal. Pheromones fall under the broader category of semiochemicals, from the Greek *semeon* meaning signal or mark, which are simply chemicals through which organisms communicate. Chemical communication is ubiquitous in the animal kingdom, with more interactions being mediated by pheromones than any other form of signal. This article introduces the diversity of chemicals that are

pheromones and outlines the general methodology used in their discovery. It then concentrates on the role of gas chromatography techniques in the analysis of volatile pheromones, comprehensively reviewing all the current methods of sampling separation, structural elucidation, and detection as applied to pheromones. The use of high-performance liquid chromatography (HPLC) in the elucidation of nonvolatile pheromones is then highlighted, followed by a brief forward look to future developments.

## The Chemical Diversity of Pheromones

Pheromones can be individual chemicals or complex mixtures of chemicals and the chemical properties of the pheromone can be directly related to its function. A sex pheromone released by a female moth to

factors, including delayed drug distribution, production of active metabolites, irreversible drug–receptor interactions (for example, the effect of aspirin on cyclooxygenase in platelets), and production of indirect therapeutic effects, complicate the elucidation of the time course of drug effect *in vivo*. In these cases, other appropriate mathematical models are available to establish a good correlation between drug concentration and pharmacodynamic effect and predict the time course of drug action under steady-state conditions *in vivo*. Since the kinetics of a pharmacodynamic effect is influenced by several factors, especially *in vivo*, it is imperative to account for both pharmacokinetic and pharmacodynamic factors when developing realistic PK–PD models with predictive value. The development of robust PK–PD models provides useful information on the nature of the pharmacological properties of drugs and kinetics of drug action *in vivo* both in preclinical and clinical investigations. At the preclinical stage, PK–PD concepts are applicable in the evaluation of *in vivo* potency and intrinsic activity, the identification of suitable markers of therapeutic effect, and optimization of dosage regimens. In the clinical setting, PK–PD concepts are useful in the characterization of the effect versus time relationship and identification of the sources of variability in drug response such as food, age, disease, gender, drug–drug interactions, tolerance development, and genetic polymorphism. Thus, PK–PD concepts provide a promising tool for

selecting new chemical entities for development and optimizing how drugs should be administered.

## Introduction

Pheromones are chemicals that transmit information between individuals of the same species evoking physiological or behavioral responses in the individual receiving the signal. Pheromones fall under the broader category of semiochemicals, from the Greek *semeon* meaning signal or mark, which are simply chemicals through which organisms communicate. Chemical communication is ubiquitous in the animal kingdom, with more interactions being mediated by pheromones than any other form of signal. This article introduces the diversity of chemicals that are

pheromones and outlines the general methodology used in their discovery. It then concentrates on the role of gas chromatography techniques in the analysis of volatile pheromones, comprehensively reviewing all the current methods of sampling separation, structural elucidation, and detection as applied to pheromones. The use of high-performance liquid chromatography (HPLC) in the elucidation of nonvolatile pheromones is then highlighted, followed by a brief forward look to future developments.

## The Chemical Diversity of Pheromones

Pheromones can be individual chemicals or complex mixtures of chemicals and the chemical properties of the pheromone can be directly related to its function. A sex pheromone released by a female moth to

attract a male several kilometers away must be highly volatile and of relatively low molecular weight (less than 300 amu), whereas an aquatic pheromone is often less volatile, of higher molecular weight, and at least partially water soluble. Clearly very different techniques are required to study volatile insect pheromones than water-soluble peptides of marine animals.

The wide variety of pheromones means that the properties and hence the structures of the chemicals involved also vary widely including alkanes, alkenes, alcohols, carboxylic acids, esters, ketones, aldehydes, peptides, and steroids. Therefore, the techniques used to study pheromones must be capable of analyzing a wide range of compounds. These analytical techniques must also be able to detect compounds in very low concentrations, as the amount of pheromone released is very low, usually nanograms or picograms. A male tree frog can attract a female from 1 m away within minutes by the release of just 40 ng of pheromone into the water. In addition, biologists often desire to determine the pheromonal composition of individual organisms, which is challenging for the analyst if the individual is an ant less than 2 mm long.

The first pheromone identified was the sex attractant of the silkworm moth *Bombyx mori*, (*E*, *Z*)-10,12-hexadecadien-1-ol or Bombykol (Figure 1). The identification of Bombykol was completed in 1959 by Adolp Butenandt after the extraction of 12 mg of the pheromone from 400 000 individuals and its structure determined by 20 years of chemical degradation reactions. In contrast, the first aquatic pheromone, the steroid 17 $\alpha$ ,20 $\beta$ -dihydroxy-4-pregnen-3-one of the goldfish, was not identified until 1987 using gas chromatography-mass spectrometry (GC-MS) techniques.

**Figure 1** 'Bombykol' the sex attractant of the silkworm moth.

(*E*)-9-Hydroxy-dec-2-enoic acid

**Figure 2** Components of the 'queen mandibular pheromone' of the honey bee.

Pheromone elucidation often starts with the observation by a biologist that a pheromone may be involved in a specific behavior of an organism. This leads to bioassays being developed utilizing crude extracts of glands or secretions which if successful are then analyzed usually after further purification. Once the chemical structure of a potential pheromone(s) has been identified, purified extracts or synthetic compounds are then used in the bioassay in order to confirm the pheromonal activity of the specific compounds.

The most common type of pheromones, termed releaser pheromones, change the behavior of the recipient and are used for a wide range of purposes including mating, alarm, attraction, recognition, and trail following. In addition, there are primer pheromones of which only one has been chemically identified, the queen mandibular pheromone in the honey bee, which leads to a physiological change in the recipient (Figure 2).

Although pheromones are known to exist throughout the animal kingdom, most of the information known about them is through the study of insects. The relative ease of studying the behavior of insects and the practical incentive of the development of pest management makes this an appealing area of research.

## Gas Chromatography

Many pheromones are multicomponent mixtures and can occur in nanogram or even picogram amounts. As a result, pheromone research demands techniques that have high-resolution and high-sensitivity capabilities. GC perhaps fulfills these requirements better than any other technique, and as a result has revolutionized pheromone research. As the majority of insect and mammalian pheromones are thermally stable, i.e., volatilize below 300°C, they are ideal for GC analysis.

As with all chromatographic techniques, GC involves the distribution of a compound between two phases, one stationary and one mobile. In GC, the mobile phase is an inert carrier gas, usually helium or hydrogen, and the stationary phase is a capillary column usually coated with a polysiloxane-bonded phase. Samples are volatilized in the injector port and directed onto the capillary column, which is heated in an oven. As the system is heated, compounds are carried through the column, and separated by volatility, polarity, and molecular weight. The resolving power of the system can be altered by the temperature program used, or by the use of different column coatings or column lengths. The capabilities of GC are further increased by the ability to connect the column to a number of different detection systems.

### Sampling and Extraction Techniques

**Solvent extraction** The lipid nature of many insect and mammalian pheromones means that they readily dissolve in pentane or hexane, or dichloromethane if a more polar solvent is required. Solvents should have a low boiling point so that they are rapidly eluted from the GC column and hence do not cover compounds present in the extract. Whole insects, insect parts, or excised glands can be soaked or crushed in the solvent, and the solution then concentrated down ready for injection. The high sensitivity of GC means that all solvents must be of the highest purity possible and any glassware or equipment used must be clean. As contamination is possible it is not uncommon for samples to be purified on silica columns prior to injection onto the GC.

**Solid sampling** A number of 'solvent-less' sampling techniques have been developed over the years in order to minimize the problems of contamination encountered with solvent extraction. Solid sampling is one such method, which allows direct insertion of biological material into the injector port of the GC. A number of solid sampling techniques have been used, one of which, the 'Keele injector', was developed by Morgan and Wadhams in 1972. In this technique, the dissected tissue, gland, or body part is sealed in a soft glass capillary. The solid sampler (Figure 3) is inserted into the injector port of the GC and the capillary is placed inside the injector and subsequently crushed, releasing the volatiles onto the column. This particular technique was used in the identification of the recruitment pheromones of the ants *Aphenogaster albisetosus* and *A. cockerelli*.

There are many benefits to the solid sampling technique including the fact that the entire sample is used, there is no dilution or contamination with

solvent, and there is no loss of quickly eluting compounds in the solvent peak. The technique also means that samples collected in the field can immediately be sealed in the capillaries, allowing samples to be easily stored and kept free from contamination.

**Volatile trapping** There are a variety of entrapment methods that can be employed in pheromone research including cold trapping, closed loop stripping, and solid adsorbent trapping. A classical way of extracting insect pheromones involves trapping airborne volatiles onto an adsorbent matrix such as activated charcoal or organic polymers (e.g., Porapak-Q and Tenax) and either eluting the compounds with solvent or through thermal desorption directly into a GC. Closed loop stripping has been adapted to sample pheromones from water such as (5R)-5-methyl-3-heptanone and the (3E,5E) and (3E,5Z) isomers of 3,5-octadien-2-one, which induce egg release in the marine polychaete *Platynereis dumerilli*.

Solid-phase microextraction (SPME) is a relatively new method of volatile trapping, and uses a length of fused silica fiber coated with a polymer material or solid adsorbent. The use of SPME in pheromone research was first reported in 1995, and since then has rapidly grown in popularity. Compounds are adsorbed onto the fiber from the headspace above the organism or simply by rubbing the fiber on the surface of the tissue. Pheromones in solution, either aqueous or organic, are adsorbed on to the fiber simply by dipping it into the solution containing the compounds being analyzed. Desorption of the compounds occurs when the fiber is heated in the injector port of a gas chromatogram. SPME provides many advantages over other sampling techniques as it is very simple, takes only a few minutes, and uses no solvent. In studies on the male pheromone of the asparagus fly, the fiber trapped the emission of a single fly after exposure for only 1 min. The other major advantage of SPME is its nondestructive nature allowing repeat sampling of the same organism, which was previously not possible. It also means that samples can be taken from living organisms with few disturbances to the organism and its environment.

There are a wide variety of SPME fiber coatings available. Polymethylsiloxane fibers are useful for low to medium polarity compounds and are therefore suitable for most pheromones. Mixed coated fibers are available and these are possibly more suitable for a starting point as they offer complimentary properties and are therefore suitable for a wide range of compounds. The mixed coated polydimethylsiloxane-divinylbenzene fiber offers the broadest range of adsorption.

**Figure 3** Cross-section of the Keele injector (permission from Prof. E D Morgan).

SPME has been used to sample a wide variety of compounds and organisms, including (Z)-7-dodecenyl acetate, from the female Asian elephant *Elephas maximus*, 4,8-dimethyldecanal, from the flour beetle *Tribolium castaneum*, and 2-butanol, 3-hydroxybutanone, and 2,3-butanediol, from the Rhinoceros beetle *Scapanes australis* (Figure 4).

**Microreactions** Microreactions have found widespread use in pheromone research as derivatization and functional group modification can aid chromatographic properties and MS structural determination.

Pheromones can differ simply by the position or geometry of a double bond as is seen with the female sex pheromone of the Asian elephant (Z)-7-dodecenyl acetate and the sex pheromone of the citrus fruit borer (E)-8-dodecenyl acetate (Figure 5). This therefore illustrates the need to know the exact structure of pheromones, including position and geometry of double bonds and other functional groups.

There are a number of methods used for the determination of the number and position of double bonds in unsaturated molecules. Reduction using hydrogen over palladium on carbon, or diimide

reduction can be used to determine the degree of unsaturation. Epoxidation using *m*-chloroperoxybenzoic acid has been used in the study of multi-unsaturated compounds, and was used to aid the identification of (3Z, 6Z, 9Z)-nonadecatriene, the sex pheromone of the fall cankerworm *Alsophila pometaria*. Monoepoxidation and catalytic hydrogenation produced a mixture of epoxide isomers, which allowed the double bond positions to be elucidated by the mass spectral fragmentation patterns. Cleavage in the MS occurs preferentially alpha to the epoxide. This therefore produces fragments that indicate position of the epoxide and hence the double bonds (Figure 6).

Dimethyldisulfide derivatization is the most common method used for double bond position determination. Reaction of the alkene in hexane with dimethyl disulfide (DMDS) and iodine under an inert atmosphere at 60°C produces the DMDS adduct. MS fragmentation of the DMDS derivatives occurs between the methylsulfide groups, thus locating the original double bond position (Figure 7). DMDS derivatization was used for the determination of the double bond position in (E)-8-dodecenyl acetate, the sex pheromone of the citrus fruit borer.

**Figure 4** Examples of compounds sampled by SPME.

**Figure 5** Double bond positions in the sex pheromones of the Asian elephant and the citrus fruit borer.

**Figure 6** Determination of double bond positions in multi-unsaturated compounds by epoxidation (*m*-CPBA) and reduction (Pt/alumina and  $H_2$ ).

Carboxylic acids are highly polar and reactive substances and do not lend themselves well to gas chromatography, although they can be analyzed on a polar column. Analysis of acids is usually achieved through conversion to methyl esters, or diphenyl esters, which are excellent subjects for GC. Diazomethane is a common methylating reagent resulting in clean and highly selective reactions. The disadvantage of using diazomethane is that it does have explosive and toxic properties. Boron trifluoride in methanol is also used to methylate carboxylic acids and is a very straightforward procedure without the explosive nature of diazomethane.

### Separation and Columns

The majority of insect and mammalian pheromones are small and relatively simple molecules with low polarity. Nonpolar polysiloxane phases such as 100% polysiloxane or 5% polyphenylmethyl siloxane are the preferred column for pheromone research due to a broad range, thermal stability, and long lifetime. Five per cent (phenyl)methylpolysiloxane columns were used in the identification of dodecenyl acetate and dodecenol, the sex pheromones of the citrus fruit borer, and anisole, the sex pheromone of the scarab beetle. A 100% polysiloxane column was used in the analysis of dodecenyl acetate, the female sex pheromone of the Asian elephant.

Mixtures of pheromones can often be complex and demanding to separate, particularly when isomers of molecules are present. This is particularly acute in the study of social insect cuticular hydrocarbons and which are often complex mixtures of 50 or more different hydrocarbons of increasing chain length (Figure 8). For these mixtures the separation of isomeric hydrocarbons such as 9-, 11-, and 13-methylheptacosane is not possible, which has a consequent impact on peak integrations and statistical correlation of these data with colony function.

If better separation is required for more polar compounds a column with a polyethylene glycol phase can be used, as used in the studies of the termite trail pheromone dodec-3-en-1-ol. These phases are also particularly suitable for the separation of carboxylic acids, oxo-acids, lactones, ketones, and polar heterocyclic molecules as seen in the analysis of the metapleural gland secretion of the leaf cutting ant *Acromyrmex insinuator* (Figure 9). It may also be necessary to use more than one column in order to fully separate and identify compounds. In studies on the aggregation pheromone of the sugar cane weevil, both a 5% phenyl methylpolysiloxane column and a polyethylene glycol column were used for identification purposes.

**Figure 7** General scheme for dimethyl disulfide (DMS) derivatization of double bonds.

Chiral columns are also employed in pheromone research for the determination of the absolute configuration of stereoisomers. The configuration of 4-methylheptan-3-ol and 4-methylheptan-3-one, sex pheromones of the oak bark beetle, were determined using a fused silica column coated with octakis [6-O-methyl-2,3-di-O-pentyl]- $\gamma$ -cyclodextrin. The elution order of the ketone stereoisomers was determined according to the literature and the natural compound was found to be (*S*)-methylheptanone. The absolute configuration of the alcohol present in the insects was determined by comparison with authentic standards and was found to be (3*R*, 4*S*)-methylheptanol.

## Detection

**Flame ionization detection (FID)** The most simple detection technique used with GC is FID, which can detect as little as 1 ng of compound. As the analyte enters the detector it passes through a hydrogen flame, which creates a current between two electrodes, producing a signal. Retention indices such as Kovats indices or equivalent chain length can be used to determine chain length and possible identification of compounds (Figure 10). The major disadvantage with FID is that there is no structural information provided, which means that identification can never be definite.

**Mass spectrometry** The combination of GC and MS provides an extremely powerful tool for the study of pheromones. The mass spectrometer is a highly sensitive instrument, normally being able to detect as little as nanogram or picogram amounts. The most important feature of MS is that it provides important structural information including a characteristic fragmentation or 'fingerprint'. Fragmentation patterns are specific for groups of compounds and therefore spectra can be compared to spectral

libraries and standard samples. Gas chromatographs are easily connected to mass spectrometers with the capillary column passing through a heated 'transfer line' into the ion source of the mass spectrometer.

The mass spectrometer ionizes molecules causing them to fragment, creating a characteristic group of ions of different masses. Electron ionization (EI-MS) is most commonly used, employing a stream of electrons, which bombards the sample molecules causing radical ions to be formed, and the molecule to fragment. Fragmentation patterns from EI-MS provide a great deal of structural information and often sufficient to allow the identification of compounds. GC-MS has therefore been used in the identification of countless pheromones in both insects and mammals.

The trail pheromone of the ant *Tetramorium meridionale* was successfully identified by EI-MS. The pheromone was found to be made up of four compounds: 2,5-dimethylpyrazine, trimethylpyrazine, 3-ethyl-2,5-dimethylpyrazine, and indole (Figure 11). The compounds were only present in picogram amounts, and all four were required to elicit a response in biological testing thus illustrating both the detection and separation powers of GC-MS.

Chemical ionization (CI-MS) employs a reagent gas, which is introduced into the ion source creating ions to react with the sample molecules. Although abundant molecular ions are usually seen, only simple fragmentation patterns and limited structural information is obtained. CI-MS, therefore, is generally used in addition to EI-MS to give accurate molecular ions or to elucidate specific structural features. For example, ionization of mono-enes using an ion-trap mass spectrometer and acetonitrile as the reagent gas gives rise to two characteristic fragment ions from which the position of a double bond can be located.

Finally, gas chromatography-time-of-flight mass spectrometry (GC-TOF-MS) is now finding its way

into pheromone research with the added advantages of higher sensitivity and the ability to obtain accurate mass data.

**Electroantennographic detection (EAD)** EAD is an electrophysiological technique that is specifically

used in the chromatography of insect pheromones involving the use of an excised antenna or whole insect. EAD measures the change in potential between the tip and base of the antenna as odors are passed over it giving a relative measurement of the number of chemoreceptors stimulated.

**Figure 9** Gas chromatogram of a metapleural gland of *Acromyrmex insinuator* using a 'carbowax' polyethylene glycol column (data from J E Parker).

#### Kovats indices

$$KI_x = 100 \times \left( \frac{\log(rt_x) - \log(rt_n)}{\log(rt_{n+1}) - \log(rt_n)} \right)$$

$KI_x$  = Kovats indices of unknown peak,  $x$   
 $rt_x$  = Retention time of peak,  $x$   
 $rt_n$  = Retention time of preceding  $n$ -alkane  
 $rt_{n+1}$  = Retention time of next  $n$ -alkane

#### Equivalent chain length

$$ECL_x = n + \left( \frac{(rt_x) - (rt_n)}{rt_{n+1} - (rt_n)} \right)$$

$ECL_x$  = Equivalent chain length of unknown peak,  $x$   
 $n$  = Chain length of preceding  $n$ -alkane  
 $rt_x$  = Retention time of peak,  $x$   
 $rt_n$  = Retention time of preceding  $n$ -alkane  
 $rt_{n+1}$  = Retention time of next  $n$ -alkane

**Figure 10** Equations for Kovats indices and equivalent chain length.

**Figure 11** Components of the trail pheromone of the ant *Tetramorium meridionale*.

Coupling of EAD to GC was first achieved in 1969, and further developed in 1975 in studies on the sex pheromone of the European grape vine moth. The use of capillary columns allowed a continuous stream of the GC effluent on to the antenna, which had previously not been possible. The GC effluent can be split between the EAD and an FID allowing the correlation of biological response to identified compounds (**Figure 12**). Recent studies on the Egyptian armyworm found that the use of the whole insect provides better results than the use of the excised head, or the antenna, and showed that as little as 15 pg of compound could be detected.

The use of GC-EAD allows the rapid screening of compounds and extracts in order to identify those eliciting a response and eliminate those not detected by the insect. GC-EAD takes full advantage of the separation capabilities of GC together with the detection capabilities of the EAD. Stereochemical determination can also be achieved using GC-EAD, and the use of chiral stationary phases allowed the stereochemical identification of the sex pheromone of the brown-banded cockroach.

A further extension of GC-EAD is the use of single cell recording when the response of an individual olfactory cell is monitored. The basic set-up is the

**Figure 12** GC-FID trace (top) and GC-EAD responses of a male citrus fruit borer (bottom) to hexane extracts of female abdominal tips. (Reproduced with permission from (2001) *Journal of Chemical Ecology* 27(10): 2041–2045 (figure 2); © Kluwer Academic Publishers.)

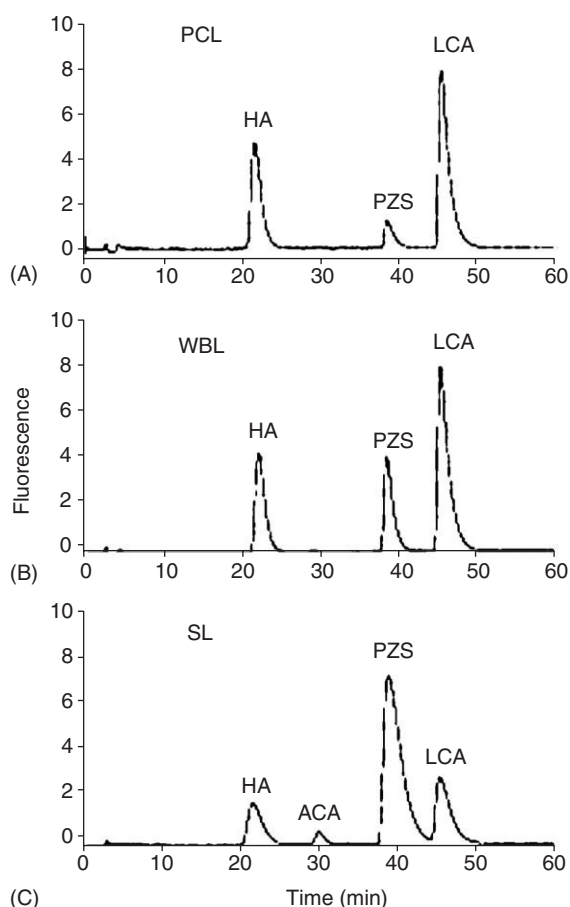

same as in EAD; however, fine tungsten electrodes and micromanipulators are used in order to position a recording electrode at the base of an antennal sensilla.

## High-Performance Liquid Chromatography

Insects have been ideal organisms on which to carry out semiochemical studies and as a majority of their pheromones are volatile or semivolatile they are particularly suited to GC–MS analysis. This, coupled with the slower introduction of LC–MS explains why the use of HPLC in pheromone identification is more limited; however, this is changing. A recent report used the greater resolving power of chiral LC compared to chiral GC to directly measure the natural ratio of enantiomers of (*Z,Z*)-*cis*-3,4-epoxy-6,9-nonadiene, the female sex pheromone of the Japanese giant looper moth. This article also suggests that with the use of microcolumns LC–MS has the potential to rival GC–MS for sensitivity, thus taking HPLC out of its previous use of prefraction prior to GC–MS analysis and the purification and separation of synthetic pheromones.

A wide range of reversed phase (RP) stationary phases are available for use and for preliminary investigations use of a standard octadecyl (C-18, ODS) phase is recommended along with running a standard gradient of water/acetonitrile. A number of different detectors can be incorporated into the HPLC system, the most common being ultraviolet – visible, fluorometric, amperometric, and mass spectrometric. Generally, mass spectrometers have an electrospray ionization (ESI) source, which is good for molecules of a molecular weight above 300 amu and can be used in both negative and positive modes.

There has been biological evidence for the existence of pheromones in marine species since the 1960s

**Figure 13** Chromatograms of gall bladder extracts from the Pacific lamprey (A), western brook lamprey (B), and sea lamprey (C). Petromyzonol sulfate (PZS) and allocholic acid (ACA) cleanly separate from each other and hyocholic acid (HA) and lithocholic acid (LCA) are the internal standards. (Reprinted with permission from *Steroids*, 68 (2003) 515–523; © Elsevier.)

and from the late 1980s. HPLC and LC–MS have been applied to the elucidation of their chemical structure. For example, steroidal bile acids have been identified in a number of *Lampetra* species using RP-HPLC. Petromyzonol sulfate and allocholic acid have been confirmed as a migratory pheromone in the larval sea lamprey and the related 3-ketopetromyzonol sulfate as a male sex pheromone. To aid detection the HPLC eluent was mixed with buffered NAD, dithiothreitol, and ethylenediaminetetraacetic acid using a tee and passed down a column of immobilized 3 $\alpha$ -hydroxy-steroid dehydrogenase column and the resulting NADH detected fluorometrically (**Figure 13**). Similarly, RP-HPLC has been used in the purification of a number of peptide pheromones such as attractin, a 58-residue protein sex pheromone produced by the female mollusk *Aplysia californica*.

Amphibian species have also been found to use peptide and protein pheromones. For example, the structure of the decapeptide sodefrin, the first peptide

pheromone identified in a vertebrate, was isolated from male red-bellied newts in 1995 using RP-HPLC purification. Similarly, a number of pheromones from male and female tree frogs have been separated and identified using RP-HPLC and ESI-MS/MS.

## Future Developments

The analysis and identification of pheromones is a diverse and complex area of research. The use of GC and GC-MS is well established and provides sensitive and reliable methods of analysis for a majority of volatile pheromones. The development of fast GC techniques and two-dimensional separations are likely to have an impact in the near future. The increased sensitivity of mass spectrometers will further improve the limits of detection and GC-TOF-MS provides a fast and efficient means of obtaining accurate mass data. The coupling of GC to EAD allows the fast screening of compounds for biological activity, and the introduction of SPME provides a reliable method for sampling live individual organisms with the minimum of disturbance. Increasingly, LC-MS techniques are now finding uses in the field of pheromone research, particularly in the identification of nonvolatile pheromones. This trend is likely to continue and over the next decade it is anticipated that the diversity of species in which pheromones are known will further expand.

## Introduction

The emission of visible or ultraviolet (UV) radiation by matter is due to spontaneous radiative decay of electronically excited atoms or molecules. Thus, such emission entails that the emitting matter loses energy in the form of electromagnetic radiation and therefore some form of energy must be supplied for a

continuous emission of radiation. 'Incandescence' is the process in which the emission of radiation is sustained by simple heating, e.g., a hot body emits light. All other forms of light emission by matter can be included under the more general term of 'luminescence' and the most common, and analytically most useful, type of luminescence is 'photoluminescence', in which the necessary energy is supplied by an external exciting light. The two sister techniques, fluorescence and phosphorescence, derived from photoluminescence phenomenon are the result of two basic processes: absorption (excitation) of light and spontaneous emission of light from the matter studied.

Historically, one of the first known references on luminescence dates from the Chinese literature of the years 1500–1000 BC, where the phenomenon of light coming out from different types of glowworms is described. However, it appears that the first reported observation of photoluminescence can be traced back to the sixteenth century when a Spanish physician and botanist, Nicolás Monardes, reported a blue tint that appeared in the water contained in cups of a special type of wood. Edmond Becquerel (1820–91) was, during the nineteenth century, the most important researcher on phosphorescence phenomenon: he not only obtained the excitation and emission spectra from different phosphors, but also performed many different fundamental studies including the effect of temperature or the measurement of the emission time of the phosphorescence phenomenon and established a exponential law to explain the decay of the phosphorescence emission. For such purposes he built in 1858 the first phosphoroscope that was able to measure lifetimes as short as  $10^{-4}$  s.

The term 'photoluminescence' and the first report of phosphorescence, however, was made by Eilhardt Wiedemann in 1887, who observed the phosphorescence of aniline dyes in solid solutions and in gelatin.

However, the satisfactory explanation of phosphorescence as a radiative transition from the lowest triplet state had to wait till the decisive paper of G.N. Lewis and M. Kasha in 1944. Moreover, considering that the characteristics of the phosphorescence phenomenon, in terms of wavelengths, triplet lifetime, quantum yield, etc., are specific of the emitting molecule, these authors also suggested the potential of phosphorescence for the individual identification of organic compounds in complex mixtures.

Analytical low-temperature phosphorimetry was mainly developed during 1960s by the group of J.D. Winefordner, after the pioneering paper by Kiers and co-workers that appeared in 1957.

We will concentrate here on the basic principles, instrumentation, and experimental factors affecting

the phosphorescence signals observed. A brief survey of low-temperature phosphorimetry (LTP) and some selected applications will also be included. The analytical potential and scope of room-temperature phosphorescence (RTP), not fully disclosed until the 1970s, are dealt with elsewhere in the encyclopedia.

## Photophysical Basis of Phosphorescence

The general theory of molecular photoluminescence is discussed elsewhere in this encyclopedia. Thus, only the principles pertinent to phosphorescence will be revised here in the light of the basic processes that can take place in molecular luminescence, and these are shown schematically in **Figure 1**. A phosphorescent emission originates as a radiative transition from the lowest triplet state to the ground state, according to the following mechanism: the molecule is originally in one of the vibrational levels of the electronic ground state. After the absorption of electromagnetic radiation of appropriate frequency in the UV or visible region, the molecule is 'excited' to an upper energy level of the same multiplicity; that is, as the ground state is usually a 'singlet' state (all the electron spins are paired and so in opposing directions) the most probable excitation by electromagnetic radiation is that promoting the molecule to a vibrational level of some of the excited electronic singlet states,  $S_1$ ,  $S_2$ , etc. Direct excitation to triplet states,  $T_1$ ,  $T_2$ , etc. (where the electron spins are parallel) is most unlikely because the transition  $S_0 \rightarrow T_1$ ,  $T_2$ , etc., involves a change in the electron spin and so is a spin-forbidden transition. Therefore, excitation of the molecule always takes place via singlet–singlet transitions. These are of such high probability that the time to pass from the ground state to the excited singlet states is  $\sim 10^{-15}$  s (a period so short that, according to the Franck–Condon principle, such electronic transition do not essentially modify the relative positions of the atomic nuclei of the molecule). But if phosphorescence is a triplet→singlet transition, how is the triplet state populated?

Once excited by electromagnetic radiation, the molecule relaxes very quickly, via vibrational relaxation and internal conversion processes, down to the lowest vibrational level of the lowest excited singlet state,  $S_1$ , from where fluorescence originates. If there is spin–orbit coupling between an excited singlet state and an excited triplet state, the vibrational levels of  $S_1$  overlap with the higher vibrational levels of the triplet  $T_1$  and a mixing of states results that removes the original spin-forbidden character of such

**Figure 1** Simplified energy level diagram of an organic luminescent molecule showing basic photophysical processes.  $K_{rv}$ , rate of vibrational relaxation processes,  $K_p$ , rate of phosphorescence,  $K_q$ , rate of quenching.

$S_1 \rightarrow T_1$  transitions, favoring the process of ‘intersystem crossing’ between similar energy levels (the time for intersystem crossing is  $10^{-4}$ – $10^{-12}$  s), which can therefore compete favorably with fluorescence (decay time,  $10^{-9}$ – $10^{-7}$  s). Therefore, the process of ‘intersystem crossing’ is crucial to populating the triplet states (and so to observe phosphorescence). The molecule will then undergo rapid vibrational relaxation and perhaps internal conversions to arrive at the lowest vibrational level of the lowest excited triplet state. Once there, a most peculiar spin-forbidden radiative transition  $T_1 \rightarrow S_0$  (lifetime  $10^{-4}$ – $10^2$  s) can take place, bringing about ‘phosphorescence’, which is the emission of electromagnetic radiation of energy  $E = h\nu$ , corresponding to the  $T_1 \rightarrow S_0$  energy gap.

As shown in **Figure 1**, there are two processes to be considered and minimized for observation of strong phosphorescence: ‘reverse (or inverted) intersystem crossing’ and quenching of the phosphorescence. As a rule the intrinsic rate constants of intersystem crossing  $S_1 \rightarrow T_1$  are orders of magnitude greater than for the  $T_1 \rightarrow S_0$  transitions because the energy gap is smaller and the probability of vibrational levels overlapping is greater in the former case.

In the light of this ‘pumping’ or ‘populating’ of the triplet mechanism, the main distinguishing features of phosphorescence versus fluorescence become clear:

1. As the triplet  $T_1$  lies lower than  $S_1$ , the phosphorescence emissions will appear at longer wavelengths than those of fluorescence.
2. Any factor or manipulation that favors the  $S_1 \rightarrow T_1$  rate constant, e.g., heavy atoms, will

decrease the fluorescence intensity while, as a rule, it will increase the phosphorescence intensity.

3. Phosphorescence originates as a result of a spin-forbidden transition. Therefore, decay times of phosphorescence are orders of magnitude longer than those of fluorescence (lifetimes of  $10^{-4}$ – $10^{-2}$  s as compared to  $10^{-9}$ – $10^{-7}$  s).

The long lifetimes in phosphorescence are most useful for achieving improved analytical selectivity for three main reasons. First, the measurement of phosphorescence sufficiently delayed from the excitation process permits the elimination of possible spectral interferences caused by fast processes such as Rayleigh or Raman scattering and fluorescence emissions. Second, it is easy to differentiate among several phosphorescent molecules or even to identify them just by measuring their lifetimes, which are characteristic in given environments (time-resolved phosphorimetry). Third, phosphorescence provides multidimensional information (excitation and emission spectra, intensity of emissions, lifetimes, and even polarization characteristics) in a straightforward manner. Such information can be used conveniently, with the aid of chemometrics, to resolve the analysis of difficult mixtures without previous separation.

The long lifetimes of phosphorescence are also responsible for the main drawback of the technique: the emission is much more critical and less intense than conventional fluorescence. Because the rate of phosphorescence decay is so slow, the probability of occurrence of other competing processes increases

substantially. As well as reverse intersystem crossing  $T_1 \rightarrow S_1$  (see Figure 1), in particular collisional deactivation of the excited triplet state by solvent molecules and impurities, especially dissolved oxygen, will become most effective. In fact, the probability of triplet deactivation by collisions (quenching) is so high for an excited molecule in solution and at room temperature that phosphorescence in such conditions is very rare (observed only under special circumstances). For this reason, it was believed initially that the only way to obtain analytically useful phosphorescent signals was by dissolving the phosphor molecule in a solvent that was then frozen at the temperature of liquid nitrogen (77 K) to form a rigid glass in which motion, and so external collisions (quenching), would be hindered.

Practical analytical work with such cryogenic techniques is complex and cumbersome and this has deterred general acceptance of the technique by the analytical community (except for some special applications that are reviewed later). However, several advances have made it possible to obtain strong phosphorescence signals at room temperature, even in oxygenated liquid solutions, opening new possibilities for analytical spectrometry applications.

Apart from the peculiarities derived from the triplet state deactivations, the main basic parameters (concepts) that describe a phosphorescent emission are virtually the same as those that describe fluorescence emissions. The most important of those parameters, their concepts, and dependences on intrinsic and extrinsic factors (via simple formulae) are summarized in Table 1.

## Factors Affecting the Phosphorescence Signal: Basis of Quantitative Analysis

As in fluorescence, phosphorescence signals depend upon both structural and environmental factors. Under appropriate experimental conditions, the intensity of the phosphorescent emission measured is linearly related to the concentration of the phosphor. This relationship, which constitutes the theoretical basis of quantitative phosphorescence analysis, is very similar to that obtained for fluorescence, except that the efficiency of 'intersystem crossing', which populates the triplet, should also be taken into account. Therefore, at very low concentrations of the analyte (trace analysis), the basic equation is

$$\Phi_P = 2.303(\Phi_T \Phi_{PP}) I_0 \epsilon l c \quad [1]$$

(see Table 1 for definition of terms).

Although theoretical expressions like eqn [1] under experimental conditions can become rather complex, or have not been fully developed, the basic equation (eqn [1]) is most useful for simple systems. It demonstrates that for a given phosphor ( $\epsilon$  is constant at a given wavelength) under constant experimental conditions in dilute solutions, there is a linear relationship between the property measured,  $I_P$ , and concentration,  $c$ , of the phosphor. It shows us that one way to increase the analytical signal is by resorting to instrumental parameters optimization. In fact, increasing the excitation slitwidth or lamp intensity ( $I_0$ ) or increasing the pathlength would result in an increase of  $I_P$  for a given concentration of the phosphor. Equation [1] also shows that the analytical

**Table 1** Important photophysical parameters<sup>a</sup> in phosphorescence

Phosphorescence parameter	Concept	Basic formula
Quantum yield, $\Phi_P$	Photons emitted as phosphorescence/photons absorbed from excitation	$\Phi_P = \Phi_T \frac{K_P}{K_P + K_{UD} + K_{PQ}}$ $= \Phi_T \Phi_{PP}$
Intensity (continuous emission measurement), $I_P$	The analytical signal measured at a given wavelength bandpass, $\Delta\lambda$	$I_P = 2.3\Phi_P I_0 \epsilon l c \quad (\epsilon l c < 0.01)$
Lifetime, $\tau_P$	Time required for the emission to decrease to $1/e$ of its initial ( $t=0$ ) intensity at given conditions	$\tau_P = \frac{1}{K_P + K_{UD} + K_{PQ}}$
Intrinsic lifetime, $\tau_P^*$	Lifetime of the triplet in the absence of radiationless deactivation processes ( $\Phi_P = 1$ )	$\tau_P^* = \frac{\tau_P}{\Phi_P} \Phi_T = \frac{1}{K_P}$

<sup>a</sup>  $\Phi_T$  = quantum efficiency for triplet,  $T_1$ , formation;  $K_P$  = rate of phosphorescence;  $K_{UD}$  = rate of radiationless unimolecular  $T_1$  deactivating processes;  $K_{PQ}$  = rate of phosphorescence bimolecular quenching;  $I_0$  = intensity of the excitation radiation;  $\epsilon l c$  = absorbance of the sample solution;  $c$  = analyte concentration;  $l$  = pathlength through sample for absorption;  $\epsilon$  = molecular absorptivity.

signal can be increased by optimization of the microenvironment that surrounds the phosphor. Any manipulation of the environment that favors the process of intersystem crossing,  $\Phi_T$  (e.g., a change of solvent or by addition of heavy atoms such as  $\text{Pb}^{2+}$  or  $\text{Tl}^+$ ), will increase the analytical signal  $I_P$ .

According to eqn [1],  $I_P$  would also be increased by optimizing the experimental conditions to protect the populated triplet from radiationless deactivation by collisions with impurities of the solvent itself. Phosphorescence demands radiational deactivation of the triplet. Unfortunately, however, owing to its long lifetime, the triplet is prone to many deactivation processes possible in fluid solution at room temperature (where collisions are very probable). In fact, in such experimental conditions the value of

$$\Phi_{PP} = \frac{K_P}{K_P + K_{PQ}}$$

(see Figure 1) is close to zero because the velocity constant of the quenching processes,  $K_{PQ}$ , is much higher than the corresponding constant of the phosphorescence process ( $K_{PQ} \gg K_P$ ). If we wish to increase the phosphorescence quantum efficiency,  $K_{PQ}$  should be minimized. This can be achieved by resorting to protecting the phosphor in a more or less rigid medium, as is the case in rigid matrices (low-temperature rigid glasses, high-viscosity solvents, fluid-organized media, and solid substrates) where collisional deactivations are thus hindered. In this way,  $K_{PQ}$  may become smaller than  $K_P$  and so analytically useful phosphorescence can be obtained.

Other environmental factors that should be controlled are the presence of possible impurities with quenching properties (e.g., oxygen), the solvent used, and the pH value if the luminescent molecule exhibits acid-base properties. It is interesting to note that heavy atoms, but particularly paramagnetic species (e.g., oxygen and nitric oxide) can enhance both intersystem crossing and quenching of the triplet state, rendering it very difficult to predict the overall effect on phosphorescence signals observed.

For a complete picture, we should briefly refer to the influence of the chemical structure of the emitting molecule. As with fluorescence, aromatic compounds are most important because they may yield phosphorescence. A shift of this emission toward longer wavelengths with an increase in the number of condensed benzene rings is observed. Introduction of a heteroatom into the aromatic electron system (e.g., in a polyaromatic hydrocarbon) or substitution by atoms of high atomic number (e.g., the internal 'heavy-atom' effect of bromine or iodine) usually

increases the phosphorescence observed as both factors tend to enhance the rate of intersystem crossing and so of  $\Phi_T$ .

Phosphorescence of aliphatic compounds is rarer, with the exception of biacetyl ( $\text{CH}_3\text{CO}-\text{COCH}_3$ ), which gives strong phosphorescence, and some aliphatic ketones that have been shown to phosphorescence with lifetimes on the order of a few milliseconds.

It should be stressed, finally, that phosphorescence of an analyte, or its derivatized compound, is a rather complex process that can be affected drastically by slight modifications of the chemical structure or small variations of the chemical nature of the environment.

## Basic Instrumentation for Phosphorescence

The detection and measurement of phosphorescence signals requires a photoluminescence spectrophotometer. The basic instrument for phosphorescence is essentially a fluorimeter with five basic components:

1. A light source (e.g., a xenon lamp, a laser, a light-emitting diode).
2. Two dispersive devices (optical filters of various types, monochromators) that will allow selection of the appropriate excitation and emission wavelengths.
3. A sample compartment, where the sample cell is positioned for measurements (alternatively the implementation of optical fiber devices, which have gained recently an increased popularity in commercial instrumentation, allow to carry the excitation light from the source to the sample, and to collect the emission).
4. A transducer, such as a photomultiplier tube (or a multichannel charge-coupled device, CCD) that will convert the light intensity into electric current magnitude.
5. A data-readout device (an analog or, more usually today, digital recoding system).

Such an instrument measures total luminescence emitted, and so there is a need to distinguish between fluorescence emission and the desired phosphorescence signals. This is usually accomplished by taking advantage of the orders of magnitude differences between the characteristic lifetimes of the processes. The long-lived phosphorescence can be isolated from the shorter-lived fluorescence by resorting to a measuring system allowing out-of-phase delayed detection relative to the excitation of the sample.

The types of approaches available to do this are described below.

### Mechanically Chopped Systems: Phosphoroscopes

The 'phosphoroscope' is the simplest device for measuring phosphorescence, rejecting fast emissions such as scattered light and fluorescence. The exciting radiation is periodically interrupted by some type of mechanical 'chopper' and the emission is observed only after a time delay following the excitation cycle. Only the long-lived phosphorescence persists after a given delay time and can be measured selectively. Phosphoroscope design and mathematical expressions for the measured and instantaneous intensities of the phosphorescence were investigated in detail by O'Haver and Winefordner (see the legend of Figure 2). Two main designs of phosphoroscopes were investigated: the 'rotating can' and the 'rotating disk' or Becquerel type of phosphoroscope. These approaches, although very simple and commonly employed in the originally developed systems for phosphorescence measurements, are practically out of use today. However, considering their historical importance and didactic value a brief description of both approaches is given.

As shown in Figure 2, in the 'rotating-can' approach the phosphorescence of the sample, placed in the center of a rotating cylinder with two opposite apertures, is collected in the conventional mode at right angles to the exciting radiation. This radiation passes through the excitation shutter aperture and strikes the rotating can in such a way that one of its holes is aligned with the excitation shutter aperture the primary radiation reaches the sample cell, exciting the analyte. The holes (apertures) of the can are located in such a way that at the same moment the emission is blocked by the can wall and so no radiation

will reach the detector. As the phosphoroscope can rotate, an instant later, the excitation radiation is blocked by the wall while the other hole of the can now becomes aligned with the emission shutter aperture. In this way only phosphorescence remains while fast fluorescent and scattered radiation emissions will have decayed to negligible values after the cessation of excitation. Thus, if there is no 'delayed fluorescence' (a rare phenomenon, with longer lifetimes) only phosphorescence emissions will reach the emission monochromator and detector to be measured. For right-angled light observation, excitation takes place out of phase with the observed phosphorescent emission.

The phosphoroscope acts as an optical gating device or chopper of radiation so that the signal reaching the detector consists of a periodic series of optical pulses that are integrated in the averaged current finally measured. Therefore, this measured signal may be significantly decreased compared to that observed without the rotating phosphoroscope. The maximum rotational speed of most commercial phosphoroscopes is  $\sim 6 \times 10^3$  rpm and so the resulting cycling time of the phosphoroscope,  $t_c$ , is  $10^{-2}$  s. The ratio of the averaged DC currents observed with ( $I_P$ ), and without ( $I_{P'}$ ), the phosphoroscope is given by  $a = I_P/I_{P'}$  and depends not only on the value of  $t_c$  but also on the value of the phosphorescence lifetime,  $\tau$ , the value of the delay time,  $t_d$  (time elapsed between the end of the excitation and the beginning of the observation period) and, of course, the value of the observation time,  $t_p$ .

A less common type of phosphoroscope, not using right-angled excitation-emission geometry, is the 'rotating disk'. As shown in Figure 3, it consists of

**Figure 2** A conventional rotating-can phosphoroscope. (Reprinted with permission from O'Haver TC and Winefordner JD (1966) *Analytical Chemistry* 38: 603. © 1966 American Chemical Society.)

**Figure 3** A conventional rotating-disk (Becquerel type) phosphoroscope. (Reprinted with permission from Fischer RP and Winefordner JD (1972) *Analytical Chemistry* 44: 949. © American Chemical Society.)

two disks mounted on a common axis with excitation and emission slots aligned along the optical path. The sample tube, immersed in liquid nitrogen in a Dewar flask, as is usual in low-temperature phosphorescence (LTP), is inserted between these two disks, which have strategic openings (see Figure 3) that allow periodic delayed excitation and detection with continuous rotation of the axis.

### Electronic Systems: Pulsed-Source Gated Detector

At the beginning of the 1970s, Winefordner's group also developed the principles and instrumentation of an electronic approach for achieving time-resolved phosphorimetric measurements by resorting to the use of pulsed sources for excitation. A flash lamp, which provides pulses of short duration,  $t_f$  (e.g., 10  $\mu$ s), is operated in a synchronized manner with a specially operated photomultiplier (the 'gated-detection' system) able to 'read' the emissions from the sample that are delayed with respect to the excitation pulses. In fact, the gated detector can be turned off and on at different moments of consecutive excitation cycles: after a convenient 'delay time',  $t_d$ , has elapsed to allow for the light pulse to decay to a negligible value (see Figure 4), the detector is turned on and the phosphorescent emission is measured during a given 'gating time',  $t_p$ . The principle of operation of this electronic version of a phosphoroscope can be better explained by following a complete cycle of excitation/measurement as schematically shown in Figure 4. With an initial pulse of

exciting light, lasting  $t_f$ , the phosphorescence signal increases to a maximum and then decays exponentially. While this happens the detector is 'closed', and only after a delay time,  $t_d$  in Figure 4, is it turned on, so that only the longer-lived emissions (phosphorescence) are thus monitored for a predetermined gating time,  $t_p$ . This cycle is repeated for each pulse of the lamp and integrated photoluminescence intensity observed is measured. The delay between excitation and observation of luminescence is thus secured in order to discriminate between phosphorescence and other shorter-lived emission phenomena.

Although there are still a few commercially available instruments for phosphorescence measurements based on mechanically chopped systems, nowadays most of the commercial luminometers used for phosphorescence measurements are based on pulsed-source/gated detections. These pulsed instruments are typically equipped with a high-power xenon flash-lamp and a photomultiplier detector.

A significant instrumental development is the use of lasers for excitation. In particular, a pulsed  $N_2$  laser constitutes a most adequate source both because it is a 'pulsed' source (and this excludes the need for mechanical phosphoroscopes) and because it provides a very intense coherent radiation in the UV region at 337.1 nm that is able to excite many organic molecules. Pulsed-source time-resolved phosphorimetry is clearly advantageous compared to mechanical chopping of excitation to obtain time discrimination because (1) better signal-to-noise ratios are achieved and so lower detection limits are possible; (2) as  $t_d$  and  $t_p$  can be varied within quite broad limits, better discrimination between phosphors of different lifetimes is possible (increased selectivity); (3) they provide the ability to measure shorter lifetimes (e.g.,  $\sim 10 \mu$ s, as compared to 100  $\mu$ s for a typical rotating-can phosphoroscope); and (4) one can straightforwardly obtain the corresponding phosphorescence decay curve and thus decide on the presence of simple or complex phosphorescence systems.

In this vein, these systems also allow to perform the phosphorescence lifetime decay evaluation. After excitation of the phosphorescent molecule by the pulsed excitation source the phosphorescence decay is collected with the light detector. The signal observed in the time domain is the phosphorescence emission at various times after the excitation pulse (a multipoint decay curve is obtained from which it is possible to obtain the phosphorescence lifetime after an appropriate fitting of the obtained curve to an exponential decay function by a least squares model).

However, phosphorescence lifetime detection can be also performed in the frequency domain. In this

**Figure 4** Schematic diagram of events occurring during one cycle of sample excitation and observation in a pulsed-source gated-detector phosphorimeter. (Reprinted with permission from Fisher RP and Winefordner JD (1972) *Analytical Chemistry* 44: 950. © 1972 American Chemical Society.)

latter approach, which is becoming increasingly popular, a sinusoidally modulated excitation source (typically a laser) provides the excitation energy for the phosphorescent molecule. The phosphorescence emission from the molecule will be then also modulated but is time delayed or phase shifted, relative to the excitation signal. For a typical single exponential decay of the phosphorescence, the relationship between the lifetime,  $\tau$ , and the corresponding phase shift,  $\phi$ , is

$$\tau = \frac{\tan \phi}{2\pi f}$$

where  $f$  is the modulation frequency used.

These systems are nowadays being preferred to the most common instruments based on pulsed excitation sources for lifetime evaluation of the phosphorescence phenomenon. However, an important disadvantage of phase phosphorimetry is that the signal-to-noise ratio decreases with increasing modulation frequency, and since the phase sensitivity increases with modulation frequency, an optimal frequency has to be selected.

## Selected Applications

Most of the past analytical work in phosphorimetry has been carried out by Winefordner's research group using the technique of LTP; that is, using a solution of the sample in an appropriate solvent that is frozen at liquid nitrogen temperatures to avoid collisional quenching. In a review from this group, it is stated that, in spite of the potential of LTP in organic trace analysis, this technique has failed to attract widespread acceptance for routine applications mainly because of two major practical drawbacks. One is the need for working at cryogenic temperatures and the other is the great inconvenience involved in introducing samples in such cryogenic conditions. Different techniques of RTP have emerged during the last decade in an attempt to overcome such limitations. The characteristics and applications of such RTP techniques are discussed elsewhere in this encyclopedia.

At this point, it should be stressed that conventional LTP, notwithstanding its limitations, has been demonstrated to be an interesting tool for the analysis of many biologically and environmentally important molecules. It offers low detection limits (in the microgram per liter region), great selectivity arising from its time-resolution capability, and wide ranging analytical calibration curves.

Some low-temperature applications involving adsorption of the liquid sample on to a solid surface have been reported. However, low-temperature

solution phosphorescence, in which a long tube containing the sample solution is immersed into a special Dewar that contains liquid nitrogen (Figures 2 and 3) to cool the analyte to 77 K, is by far the most common LTP technique. Sample is dissolved in an adequate solvent (e.g., *iso*-pentane) that forms a transparent glass by cooling where the analyte is trapped in such a rigid medium. Problems associated with adequate solvent selection, immersion of the sample tube, reproducibility of the signals, etc., are serious drawbacks.

Nevertheless, analytical problems can be found where such disadvantages can be outweighed by the convenient final resolution of the problem based on LTP data. On other occasions, both fluorescence and phosphorescence data can easily be obtained from a given sample, providing complementary information. One example is the use of phosphorescence measurements at low temperature to examine mixtures of aromatic compounds dissolved in *n*-alkanes (Shpol'skii spectrometry). The narrow-band fluorescence and phosphorescence spectra complement one another and have proved most useful in the analysis of complex samples such as multicomponent mixtures of polycyclic aromatic hydrocarbons (PAHs) in fuel materials.

The first quantitative application of phosphorimetry was proposed by Winefordner's group in the 1960s for the determination of aspirin in blood by LTP. It was the first evidence that phosphorimetry could be a useful methodology for quantitative analysis in 'real' samples. Since then, LTP has proved especially useful in the determination of low levels of well-known organic pollutants. PAHs and other dangerous substances (including nitrated PAHs, polychlorinated biphenyls, a wide range of other common pesticides, and even dibenzo-*p*-dioxins) have been determined at the microgram per liter level by LTP, with precision ranging from 2% to 10%.

Different methodological advances in phosphorimetry have been developed by using LTP, including the elucidation of the effect of the presence of heavy atoms on the phosphorescence signal or the demonstration of the advantages of time-resolved phosphorimetry for the determination of individual components with different phosphorescence lifetimes in a complex mixture. In fact, a great number of biochemically important compounds and metabolites have been determined in rather complex matrices by LTP (e.g., pesticides, sulfamides, anticoagulants, carcinogenic compounds, different metabolites of triptofan, vitamins, nucleosides, DNA, amino acids, purines, cytosine, cytidine, chlorophylls, etc.), although the vast majority of published applications

refer to the analysis and control of drugs and pharmaceutical compounds. **Table 2** illustrates this, also giving analytical LTP characteristics for some selected drugs and pharmaceutical compounds.

It should be noted that although the sensitivity and selectivity of LTP are excellent, the technique was never considered as a routine technique, mainly due to the difficulties to introduce the sample for measurement and the drawback of the low temperatures required. In fact, the number of applications of LTP started to decrease from 1975. Emerging developments during the last decade came from room-temperature phosphorescence methodologies, which finally have displaced the LTP techniques.

## Introduction

The long timescales associated with phosphorescence increases the likelihood that intermolecular quenching collisions, along with possible intramolecular

vibrational–rotational relaxations, take place at room temperature, so bringing about radiationless decay of triplet states. These facts explain why for some time it was believed that only cryogenic conditions (liquid nitrogen at 77 K), hindering bimolecular quenching and intramolecular relaxations, were suitable for analytically useful phosphorescence measurements.

It has been shown, however, that phosphorescence signals can be obtained at room temperature by restricting competing deactivation mechanisms, e.g., in the gas phase at sufficiently low pressure the

frequency of molecular collisions is reduced. Quenching of the triplet state by oxygen in the vapor state can be decreased by using an inert gas and, thus, low phosphorescence intensity of some compounds can be observed. An alternative route to prevent radiationless deactivation of the triplet at room temperature is by adsorbing the phosphors on solid supports i.e., solid supports room temperature phosphorescence (SS-RTP). The use of SS-RTP for sensitive detection of 18 organic compounds was first described in 1967 by Roth. Since its beginning, the technique has been extended to numerous other species and has grown in scope, applicability, and utilization.

However, in spite of the large interest of RTP, only in the early 1980s, after the pioneering work of Cline Love, did systematic research start on the development of RTP in liquid aqueous solution when the emitting triplet molecules were incorporated into a conventional micelle under deoxygenated conditions. This phenomenon, generally referred to as micelle-stabilized room-temperature phosphorescence (MS-RTP), attracted considerable attention and rapidly found its place as a new analytical technique, allowing the use of RTP as a detection mode in flow techniques, e.g., flow injection analysis (FIA) or liquid chromatography (LC). The successful application of MS-RTP was the starting point for a large number of studies in the area and it opened up a new world of stabilized room-temperature phosphorescence procedures; thus, cyclodextrin-induced (CD-RTP), vesicle-stabilized, microemulsion-stabilized, and bio-macromolecular-stabilized room-temperature phosphorescence experimental procedures have been developed subsequently.

Room-temperature phosphorescence in liquid solutions (LS-RTP) is a further step toward practical applications of phosphorescence. The observation of RTP of biacetyl in liquid solution or that of eosin in glycerol is commonly viewed as odd exceptions to the striking and persistent failure to observe phosphorescence from organic molecules at room temperature in liquid solution. Only after several scattered reports of the observation of long-lived emission from a variety of organic dyes in deoxygenated solutions did Parker and Joyce demonstrate that the use of a carefully purified and deoxygenated special solvent (such as perfluorocarbons) allowed observation of weak LS-RTP. Although this type of LS-RTP has failed to catch on as a popular method for routine analysis, Donkerbroed *et al.* applied the technique of sensitized phosphorescence (SP) in liquid solutions as a useful alternative to direct solution RTP. The knowledge of the spectroscopic behavior of lumiphors under various conditions is crucial for the design of new RTP-based assays. As an example, the

applicability of LS-RTP is expected to change with the introduction of modern nonprotected room-temperature phosphorescence (NP-RTP), developed around the use of adequate heavy atoms in solution. An excellent review covering the analytical applications of room-temperature phosphorescence in the liquid state has been produced by Gooijer *et al.*

The sections that follow will focus on the most useful of these new analytical RTP approaches, starting with fluid solution techniques (RTP in ordered media, NP-RTP, sensitized RTP) and ending with the principles and recent applications of SS-RTP techniques.

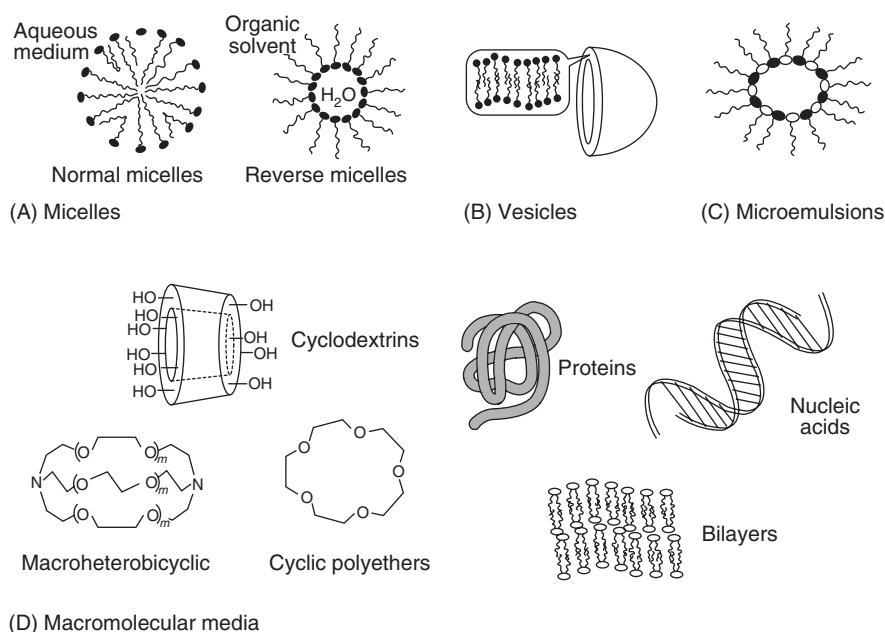

## Room-Temperature Phosphorescence in Ordered Media

### Micelle Stabilized Room-Temperature Phosphorescence

Surface-active agents are amphiphilic molecules in which a polar 'head' group is attached to a long nonpolar chain. The nonpolar moiety is usually a hydrocarbon tail and the polar region can be either an ionic or a polar neutral group. Above a certain concentration, the critical micelle concentration (CMC), these amphiphilic molecules associate dynamically in solution to form relatively well-defined aggregates termed micelles (see **Figure 1**).

Micelle characteristics depend upon the chemical structure of the surfactants and the nature of the solvent. In aqueous solution, amphiphiles assemble in such a way that the tails are packed together, forming a nonpolar core, while the polar head groups form a boundary surface between the core and the isotropic aqueous solution (normal micelles). Surfactants can also form micelles in nonaqueous solvents of low polarity. The monomers in these reverse micelles are oriented in the opposite sense to those in aqueous solutions (**Figure 1**). Anionic or cationic long-chain dialkyl surfactants generate bilayers and vesicles either by sonic dispersal in water or by gentle injection of their nonaqueous solution into pure water. Synthetic surfactant vesicles are sealed membrane capsules (**Figure 1**) that enclose aqueous volumes of 1–1000  $\mu\text{m}^3$  and compared to micellar media are much less dynamic and more stable.

These organized media possess many unique properties including their ability to solubilize, concentrate, organize, and localize solutes, to modify the spectral parameters and the effective microenvironment about solubilized molecules, to alter chemical and photochemical pathways and rates, as well as the position of chemical equilibrium processes, among other effects.

**Figure 1** Schematic representation of different ordered macromolecular systems.

Cline Love and colleagues showed that there are three fundamental requirements for observing MS-RTP for most lumophores: (1) securing the presence of micellar aggregates (using a surfactant concentration above its CMC); (2) the presence of a heavy atom or a heavy species; and (3) ensuring oxygen scavenging. The protective screening effect of micelles against external quenchers by compartmentalization of solubilized phosphor molecules greatly reduces collisional quenching of triplet molecules by quenchers. Only at surfactant concentrations well above the CMC is the protective effect on phosphorescence obvious (micellar effect). Relative phosphor-micelle charge-charge interactions are found to be also important. Negatively charged molecules in cationic micellar media and negatively charged phosphors in cationic micellar experience attractive electrostatic interactions that may concurrently act with hydrophobic ones to provide the 'rigidity' needed to observe strong RTP signals. On other hand, if micelles are 'functionalized' with a heavy atom, e.g., anionic micelles with  $\text{I}^-$ , its 'effective local concentration' within the micelle is considerably larger than its actual molar concentration. In this way the rate of intersystem crossing,  $K_{\text{isc}}$ , is greatly enhanced. At the same time, sheltered by the micelle, the nonradiative deactivation of the triplet state is prevented. Both effects result in an enhanced quantum yield of phosphorescence. By prudent choice of heavy atom and surfactant assemblies, it is possible to induce MS-RTP in a variety of compounds.

Oxygen is a most potent quenching agent of the excited triplet state. The use of an inert gas (e.g., nitrogen) to remove dissolved oxygen used to be the most common technique for oxygen scavenging, but this generates a significant amount of foam. Díaz-García and Sanz-Medel studied in great detail the use of sodium sulfite as a chemical oxygen scavenger in micellar media for MS-RTP. The technique based on the reaction  $2\text{SO}_3^{2-} + \text{O}_2 \rightarrow 2\text{SO}_4^{2-}$  is simple and reliable and is now widely accepted to develop different RTP approaches.

Among the different possibilities, normal micelles have been the organized media more commonly used to obtain RTP in fluid solution: in a classic experiment, the lumophore is dissolved in a sodium lauryl sulfate (SLS) solution and then diluted with thallium lauryl sulfate-SLS solution to give a total detergent concentration of  $0\text{--}10\text{ mol l}^{-1}$  with a 30:70 ratio of  $\text{TI}/\text{Na}$ . The solution is deoxygenated using sodium sulfite as oxygen scavenger and the sample can be analyzed using time discrimination. Most of pioneering analytical work done on MS-RTP refers to the determination of various organic compounds of significance in clinical (drugs) and environmental (polycyclic aromatic hydrocarbons, PAHs) chemistry.

Because MS-RTP permits the use of fluid solutions at room temperature, a further possibility offered by MS-RTP is that of detector in LC. This point is more interesting for analysis of body fluids, where the sample matrix produces intense background that severely reduces the signal-to-background ratio.

MS-RTP techniques can be applied to LC in two different ways:

1. The micellar phase is used as a mobile phase. In this context a typical LC/MS-RTP procedure for PAHs including naphthalene, biphenyl, and phenanthrene using an SLS/thallium laurylsulfate (70%/30%) micellar mobile phase exhibits the following features: working ranges covered more than three orders of magnitude and the detection limits were in the low nanogram range for the PAHs investigated in coal liquids and wastewater products.
2. In a postcolumn addition mode, the micellar solution is added to the mobile phase after chromatographic separation, as demonstrated also for aromatic compounds (phenanthrene, biphenyl, 2-naphthol).

Micellar eluents have been used with reversed-phase LC columns to analyze a variety of phosphor solutes by direct sample injection (e.g., serum samples). Avoidance of the sample preparation step entirely is a considerable advantage since it simplifies and significantly shortens an assay, thus improving precision. However, some factors have delayed the application of MS-RTP as detector in chromatographic separations: the foaming problems generated by nitrogen purging (which may be solved by using alternative deoxygenation schemes), the preparation of the micellar mobile phase must be carefully controlled in order to avoid eluent conditions that are unfavorable for micelle formation or favor micelle destruction. For this reason surfactant concentration must be maintained well above the CMC and the organic solvent composition should be kept relatively low (especially in the postcolumn mode).

Metal-ion MS-RTP determinations have also been demonstrated. For example, platinum(II) chelates with 8-quinolinol derivatives were found to form highly phosphorescent complexes at room temperature in the sugar-based *n*-dodecyl- $\beta$ -D-maltoside micellar medium, using iodine as heavy atom (see Figure 2).

The applicability of MS-RTP can be extended as a detection mode for metal ion determinations in flowing systems. The simplest scenario involves the use of a typical FIA configuration and a sodium sulfite deoxygenated micellar stream containing the metal–ligand lumophor, into which the deoxygenated metal ion solution is injected. After mixing, MS-RTP peaks are registered. Sulfite deoxygenation of micellar solutions greatly simplifies FIA–MS-RTP techniques.

Time-resolved phosphorimetry has also been proposed as a means of increasing the selectivity of

**Figure 2** Simplified overview of the palladium–ferron complex in sugar-based anionic micellar media.

MS-RTP metal determination mixtures. In this approach, a pulsed radiation source excites the sample and the decay profile is monitored. Thus, it provides a measure of the time dependence of phosphorescence intensity after the excitation pulse, which can also be made as a function of emission wavelength. For a binary system of components, the MS-RTP signal from a rapidly decaying species (e.g., Zn(II)–Ferron chelate in cetyltrimethylammonium bromide (CTAB) micelles) and that from a slowly decaying species (e.g., Al(III)–Ferron complex in CTAB micelles) are related through the expressions:

$$I_t^{\text{Zn}} = I_0^{\text{Zn}} e^{-t/\tau}$$

$$I_t^{\text{Al}} = I_0^{\text{Al}} e^{-t/\tau}$$

$$I_t^{(\text{Zn}+\text{Al})} = I_t^{\text{Zn}} + I_t^{\text{Al}}$$

where  $I_t$  is the total MS-RTP intensity of the mixture at a delay time  $t$ , and  $I_0$  the MS-RTP intensity at time  $t=0$ . For multicomponent systems similar expressions can be derived. Selectivity of MS-RTP for metal-ion determinations in mixtures can be further enhanced through multidimensional and mathematical approaches. Table 1 provides an overview of selected miscellaneous applications of MS-RTP.

### Cyclodextrin Room-Temperature Phosphorescence

Cyclodextrins (CDs) are macrocyclic oligosaccharides consisting of  $\alpha$ -(1,4)linkages of D-(+)-glucopyranose units arranged in a torus (see Figure 1).

**Table 1** Analytical figures for MS-RTP determination of several analytes

Analyte	Reaction medium	$\lambda_{\text{exc}}$ (nm)	$\lambda_{\text{em}}$ (nm)	pH	DL	RSD%
<i>Pharmaceutical/drug</i>						
Naproxen (anti-inflammatory)	TI (I)/SDS	330	551	7.1	$0.03 \mu\text{g ml}^{-1}$	1.2–2.1

SDS, sodium laurylsulfate; CTAB, cetyltrimethylammonium bromide; CPCI, cetylpyridinium chloride; Ferron, 7-iodide-8-hydroxyquinoline-5-sulphonic acid.

Three types of CDs are commercially available, the  $\alpha$ -,  $\beta$ -, and  $\gamma$ -CDs, composed of six, seven, and eight glucose units, respectively. CDs are cylinder-shaped molecules with an axial void cavity. Their outer surface is hydrophilic that makes them soluble in water, while the interior of the toroidal cavity is highly hydrophobic and constitutes a relatively isolated microenvironment that can selectively ‘encapsulate’ lumophores of appropriate molecular dimensions. CDs are chemically and structurally quite stable, in contrast with micellar aggregates formed by monomer surfactant units in dynamic equilibrium with the micelle.

As a result of the host–guest complexes formed by CDs with a variety of lumophores, characteristic luminescence properties of the included lumophore, sensitive to viscosity/polarity or dielectric, may change. In fact, the inclusion of a lumophore in a CD cavity has proved to provide a means of triplet-state stabilization, luminescence intensity enhancement, optical activity induction, improved solubility of poorly soluble analytes in water, etc.

As in MS-RTP, a heavy atom (external or intramolecular) or a heavy atom molecule should be present to populate the excited triplet state. In contrast to MS-RTP, an exciting feature of CDs is their seeming ability to partially protect the phosphor’s triplet state from quenching by dissolved oxygen

in solution. Nonetheless, deoxygenation of samples results in increased phosphorescence intensity.

Many interesting applications of CD-RTP have concentrated on the determination of PAHs and nitrogen-containing heterocycles. Successful applications of CD-RTP based on host size-dependent selectivity (molecular recognition) can be envisaged. For example, in  $\beta$ -CD solutions, intense RTP is observed for the smaller naphthalene (which fits neatly into the  $\beta$ -CD cavity) and no phosphorescence is detectable from a larger molecule such as 1-phenylnaphthalene.

In a typical experiment for CD-RTP analysis of PAHs an aliquot of the compound of interest is added to a flask and the solvent is evaporated gently on a hot plate. An aliquot of 1,2-dibromomethane or 2-bromoethanol (heavy-atom species) is then added, followed by an aliquot of  $0.1 \text{ mol l}^{-1}$  sodium sulfite (oxygen scavenger), and final dilution with  $0.01 \text{ mol l}^{-1}$  aqueous CD solution. The solution is shaken vigorously by hand. Some precipitation, usually due to inclusion of excess heavy atom by CD, may cause cloudiness in the solution, which does not affect the reproducibility and quality of phosphorescence spectra. Sample preparation time is less than 5 min in this method. Cline Love and colleagues reported RTP detection limits for several polynuclear aromatic compounds (naphthalene, biphenyl, phenanthrene, etc.) in CD solution in the range  $10^{-6}\text{--}10^{-7} \text{ mol l}^{-1}$ .

As in the case of MS-RTP, CD-RTP has been used as detector in LC. Unless the problems of low efficiency with CD mobile phases in chromatography are resolved, CD-RTP will not be a competitive alternative to the MS-RTP detection approach.

### Biomacromolecular Stabilized Room-Temperature Phosphorescence

Biological supramolecular assemblies such as proteins, nucleic acids, or membranes as well as single cells and tissues provide particularly useful microenvironments where lumophors (metal complexes, molecules, metal ions) can be protected or isolated from contact with neighboring quenchers. In these microdomains, molecular motions are highly restricted so that luminescence properties of those lumophors may be modified. The binding of the Pd-meso-4-(tetracarboxyphenyl)porphyrin complex to bovine serum albumin reduces the phosphorescence quenching constant by an order of magnitude. This effect can be explained as due to the protection experienced by the porphyrin complex buried inside the macromolecular structure.

Many metal complexes have been used in biological studies, most of them based on Pt- or Pd-porphyrin complexes. They exhibit strong phosphorescence in the near-infrared region (760–800 nm) and can be excited either at Soret (380–430 nm) or Q bands (500–560 nm). In order to observe RTP, oxygen must be removed from the samples. Deoxygenation schemes using chemical oxygen scavengers may result in damage of some biological structures, so enzymatic systems are recommended. To deplete oxygen in biological media a mixture of glucose and catalytic amounts of glucose oxidase/catalase can be used. The system ascorbate/ascorbate oxidase is also useful as it reduces oxygen to water without generation of hydrogen peroxide (which also may damage biological structures).

Applications of RTP probes in biological systems are typically linked to their interesting photophysical and photochemical properties. For example, the oxygen-dependent quenching of Pd-porphine complexes has been used to measure the  $O_2$  dependence of respiration by suspensions of mitochondria and cells and to develop two-dimensional maps of  $O_2$  pressure in tissues. Selective determinations of DNA in the presence of RNA can be achieved using the RTP enhancement of a Pd-porphine complex when bound to DNA. This enhancement arises from the hindered rotational motion of the DNA bound complex (Figure 3). A linear calibration graph was obtained up to  $6 \times 10^{-5} \mu\text{mol l}^{-1}$  DNA, the limit of detection being  $5 \times 10^{-8} \mu\text{mol l}^{-1}$ . The nucleic acid

**Figure 3** Pd-meso-tetra(4-crobyphenyl)porphine in a nucleic acid microdomain.

was assayed with 2.6% RSD and the method applied to DNA determination in tissues.

Pt- and Pd-coproporphyrin complexes may also be used as labels for antibodies to develop phosphorescence immunoassays. Also, RTP provides a sensitive tool for diagnosis of vascular disorders and image oxygen distribution in cancerous tissues (porphyrins are known to concentrate in tumors). Many other potential uses of RTP in biological systems include the study of processes such as rotational motion, distances, excited state reactions. RTP measurements have an important role in the study of biological systems and areas for future development are apparent.

### Sensitized and Quenched Room-Temperature Phosphorescence

'Sensitized-RTP' in solution is a method of quenching based on detection of the phosphorescence emitted by an 'acceptor'. The donor compound acts as a sensitizer, i.e., after being excited and before radiationless decay, transfers its energy to the acceptor, thus producing an acceptor triplet with a high phosphorescent yield. Sensitized-RTP has been observed for a variety of organic species (polynuclear aromatics, drugs, etc.) and compounds that do not luminescence in liquid solutions. Biacetyl and 1,4-dibromonaphthalene appear to be appropriate acceptors. Only ~10–15% of the molecules that fulfill the energy requirements are found to undergo SP.

Energy transfer between the donor and the acceptor is a probabilistic event. The ability of ordered media to bring the donor and acceptor molecules into close proximity for effective energy transfer and the partial protection of the excited phosphor provide further evidence of how the potential applications of sensitized-RTP in organized media might be. So, on dissolving the donor and the acceptor in

micellar or CD media, an enhancement of SP intensity and selectivity may occur. For benz[*a*]anthracene and anthracene determination in the presence of pyrene, for example, this approach improved the selectivity by factors as high as 200–220, when using an SLS micellar solution, thallium(I) as heavy atom, sodium sulfite as oxygen scavenger, and triphenylamine and acridine orange as triple energy donors.

A complementary technique to sensitized-RTP is quenched-RTP in solution, in which the presence of the analyte leads to a decrease of direct RTP intensity of biacetyl or other phosphorescent probes in ordered media. Energy transfer and electron transfer are the main pathways that deactivate the photoexcited state of the selected phosphors. For example, oxygen can be determined by quenched-RTP of palladium and platinum derivatives of porphyrins dissolved in ordered biological media (proteins). This approach also holds considerable potential for use in continuous-flow detector systems, including LC and capillary electrophoresis (CE), as it can be used for species that may have inherently poor detection properties by other techniques. So, it can be used to detect and quantify non-ultraviolet-absorbing compounds in ion chromatography (nitrite, sulfite, *cis*-platin, carboplatin, etc.). Also, quenched phosphorescence has been used as a highly sensitive detection mode for CE- and CD-based electrokinetic chromatography. Using conventional, lamp-based detection systems, detection limits have been reported to be in the  $10^{-7}$ – $10^{-8}$  mol l<sup>-1</sup> range and absolute detection limits  $\sim 1$  fmol. These figures are beyond the possibilities of many other techniques, especially for compounds with poor chromophores.

## Nonprotected Room-Temperature Phosphorescence

In 1997, a new concept was introduced in room-temperature phosphorescence in liquid solution: non-protected or heavy atom induced room-temperature phosphorescence, in which the presence of a protecting medium is not a necessary condition for RTP emission. The term NP-RTP seems to be more appropriate for the technique as the heavy atom perturber is a necessary condition for all RTP emission (exception made for biacetyl, which does not meet this requirement). This approach is an important technical advance, since numerous organic molecules can be determined through a very simple technique. As in all RTP methods, the following are necessary: (1) the presence of heavy atoms such as KI or TiNO<sub>3</sub> and (2) removal of oxygen (sodium sulfite has been found to be a suitable chemical oxygen scavenger).

Since its introduction, determination of several analytes and their NP-RTP characteristics have been reported, among which plant growth regulators ( $\alpha$ - and  $\beta$ -naphthoxyacetic acids), drugs, pharmaceuticals and pesticides (naphazoline, naproxen, thiazobenzodazole, carbaryl, acetamide), PAHs (fluorene, naphthalene), and other compounds (trypsin, tryptophan, indole-3-butyric acid, acridine derivatives) have been studied.

The full sensitivity potential of NP-RTP can be exploited as detector in flowing systems, as illustrated for the sensitive determination of the  $\beta$ -lactamic antibiotic nafcillin using a flow-injection approach. The NP-RTP of nafcillin was developed using potassium iodide as heavy atom promoter and sodium sulfite as oxygen scavenger. The system is capable to detect micromolar levels of nafcillin (detection limit 0.53  $\mu$ mol l<sup>-1</sup> nafcillin) and a linear calibration graph was obtained for concentrations of the antibiotic up to 85  $\mu$ mol l<sup>-1</sup>. On the other hand, and by contrast with MS- and CD-RTP, the coupling of NP-RTP with separation methods is expected to be quick and simple to perform as no micelles or CDs are necessary. However, it is known that some common organic solvents used in chromatographic separations may reduce phosphorescence in several NP-RTP systems. So, the technique may be limited to aqueous-phase separations.

NP-RTP is in its infancy and basic research on the origin of the NP-RTP phenomenon as well as the basic factors governing it have not yet been established. Looking further into the future, the technique could find many applications for both the monitoring and/or mapping of environmental or biologically important molecules.

## Solid-Surface Room-Temperature Phosphorescence

Since its introduction in 1967, the field of SS-RTP has expanded considerably. A number of organic compounds, polar and nonpolar, exhibit RTP when adsorbed on a suitable solid support. Because many of the solid supports used to develop RTP give background phosphorescence, only certain materials are useful for the task, among which sodium acetate shows the lower background emission. The phosphor molecules can be held tightly to the solid support through hydrogen bonding of polar or ionic organic compounds to hydroxyl groups of paper or to the surface silanol groups of silica gel as well as through hydrophobic interactions between the phosphor molecule and the solid network. This restriction of intramolecular rotation of the phosphor is believed

to be responsible for enhancement of the radiative decay of the triplet state ('rigidly held mechanism').

In order to observe analytically useful emissions from compounds adsorbed on paper and other solid supports, thorough drying of the sample has been found to be necessary. Moisture competes with the phosphor molecule for hydrogen-bonding sites on the adsorbent, thus increasing the mobility of the phosphor and the chances of collisional deactivation. In most cases, RTP is so sensitive to moisture that this phenomenon may be used in the determination of humidity.

It has been suggested that accessibility of oxygen to a solid surface-immobilized phosphor in a dry atmosphere is less favorable than for a wet atmosphere. Oxygen quenching efficiency is greatly enhanced in wet atmospheres as water molecules weaken the support-phosphor interactions and the integrity of the sample substrate, thus allowing oxygen to diffuse and quench the phosphor. For maximum SS-RTP intensity dry and inert environments are recommended.

The addition of external heavy-atom perturbers (such as thallium, lead, thorium, and many others) to RTP samples generally increases the radiative rate of triplet-state decay. The heavy atom effect is most striking amongst the nonionic organic compounds, where phosphorescence appears only if the heavy atom is present. The RTP intensity is highly dependent on the concentration of heavy atom perturber and significant enhancement of SS-RTP is observed when using halide salts as external heavy atom perturbers. For halides the enhancement follows the expected trend of  $I^- > Br^- > Cl^- > F^-$  with virtually no enhancement from fluoride or chloride ions and  $Tl^+ > Ag^+ > Pb^{2+} > Hg^{2+}$  for cations. Although SS-RTP spectral features are similar to those observed at low temperatures, RTP spectra generally provide less resolution owing to increased vibrational freedom of the molecules at the higher temperature. The nature of the solid support employed in SS-RTP usually has only a marginal effect on spectral features, but RTP intensity and lifetimes can be significantly affected. A considerable amount of SS-RTP research involves collecting analytical data on model compounds adsorbed on solid surfaces in the hope of developing a general working mechanism to explain the interactions required for RTP.

Significant enhancements in RTP intensity and reduction in lifetimes can be observed when the microenvironment experienced by a phosphor adsorbed onto the solid support is manipulated by the use of ordered media as solid substrate modifiers. For example, enhancements of the paper RTP sensitivity of several PAHs ranging from factors of

2 to 9 were found when an anionic surfactant was added or when the phosphors were spotted from micellar solutions. SS-RTP exhibits in all cases poorer detection limits than low-temperature phosphorescence.

Although for those nonexperts SS-RTP would hardly be the technique of choice if fluorescence is a good alternative, SS-RTP is applicable to a wide variety of compounds and samples in many areas, ranging from clinical analysis, biomedical research, pharmaceutical, agricultural chemistry, and energy technology to biomedical, environmental, and industrial control. The technique is inexpensive and small sample sizes can be employed, which is particularly advantageous for clinical and environmental samples. An excellent example of this is the determination of PAHs that are widely dispersed in the environment, often in small quantities. A striking personal dosimeter badge, based on molecular diffusion and direct detection by paper RTP of PAH vapors, at the ng per g level, with precision ranging from ~3% to 10%, has been described by Vo-Dinh, demonstrating the versatility of the technique. Hurtubise has studied in detail the best conditions to obtain solidmatrix room-temperature phosphorescence from femtomole levels of pollutants, specially from PAHs, their DNA adducts, as well as from their metabolic carcinogens (e.g., tetrols, which are products obtained from the hydrolysis of benzo[a]pyrene-DNA adducts). The limit of detection of the benzo[a]pyrene-DNA adducts was reported to be two adducts in 107 bases using both Whatman 1PS paper and a 30%  $TiNO_3/NaOAc$ . It should be mentioned that there are very few methods for the direct determination of benzo[a]pyrene-DNA adducts and SS-RTP offers the advantages of sensitivity, selectivity, no radioactive materials are used and it is developed in mild room-temperature conditions.

Another example of the power that SS-RTP affords can be seen in the use of time-resolved phosphorimetry to distinguish several phosphors with overlapping spectra but with different lifetimes such as PAHs. Two major revisions on the SS-RTP field have been produced by Hurtubise and Vo-Dinh.

SS-RTP exhibits in all cases poorer detection limits than low-temperature phosphorescence. However, it is potentially useful as a routine analytical method because (1) no cryogenic equipment, expensive and rather cumbersome to use, is needed; (2) no time-consuming degassing of the solvent is mandatory; and (3) chromatographic separations can be performed on the substrate before the analysis. These features make SS-RTP particularly suitable to exploit new detection schemes. So, SS-RTP is a convenient means of observing delayed fluorescence in those

compounds with close enough spacing between  $S_1$  and  $T_1$  levels since adequate thermal energy is available to the molecule to promote reverse inter-system crossing in this situation.

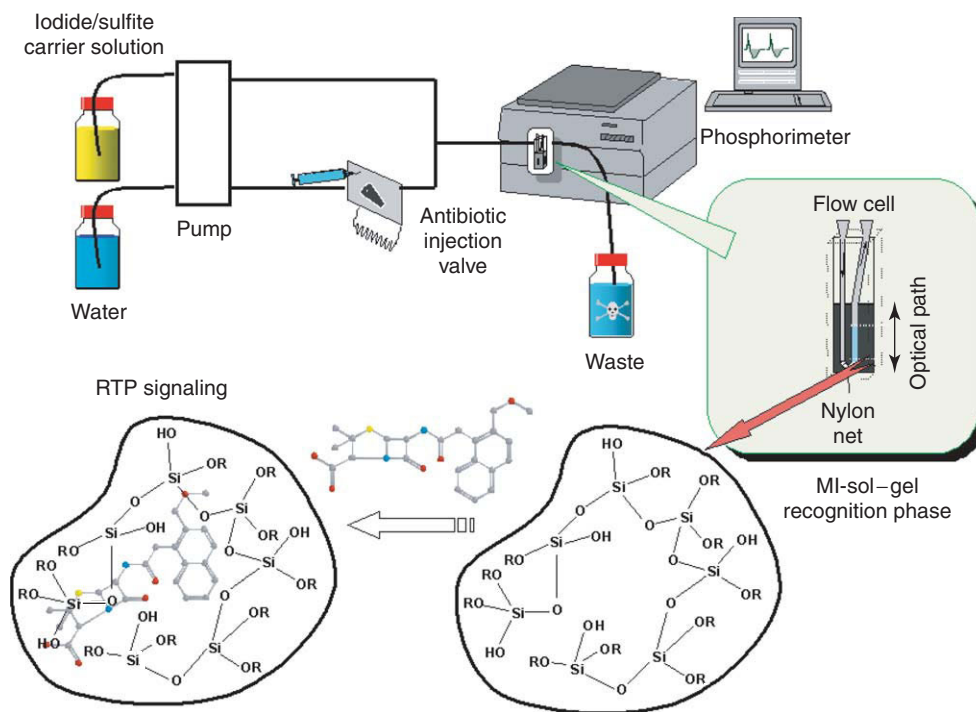

The need for real-time measurements and the development of fiber-optic technology gave the basis for designing optical sensors by monitoring changes in the RTP of phosphors immobilized on a solid support on the tip of an optical fiber. Limits of detection at the ng per ml level were estimated for pyrene, coronene, 2,3-benzofluorene, 1,2:3,4-dibenzanthracene, benzo[e]pyrene, and benzo[ghi]perylene, and the feasibility of monitoring PAHs in aqueous media was demonstrated.

In its conventional form, SS-RTP detection is not well suited for aqueous flow techniques (in contrast to homogeneous solution RTP) because of the strong quenching by moisture and oxygen and the intrinsically discontinuous character of the technique. Although the use of flow injection for continuous sample introduction in SS-RTP has been proposed, this methodology is not continuous in the flow because it involves sample nebulization on a paper strip followed by a drying step before the final measurement of the RTP signal.

In response to the demand for developing new SS-RTP methodologies for the continuous and *in situ* monitoring of different analytes, the coupling of SS-RTP to flow-injection systems was successfully

demonstrated. The approach involves the integration of the basic reaction/retention/detection process at the solid support packed into a flow cell. This detection principle in flow analysis is known as optosensing at active surfaces. To illustrate the concept, the molecular recognition of nafcillin, a  $\beta$ -lactamic antibiotic, is based on the transient immobilization/ RTP detection of nafcillin on an imprinted sol-gel material packed in a flow cell (Figure 4). Chemical deoxygenation by adding of sodium sulfite was employed. The immobilization process onto the imprinted material (insert in Figure 4) is produced by hydrogen bonding and electrostatic interactions between the template (nafcillin) and the selective recognition points inside the sol-gel. The phosphorescence properties of nafcillin are used for RTP signaling purposes. The analytical performance of this SS-RTP optosensing scheme compares favorably with other luminescent methodologies developed for nafcillin in micellar media.

There are very exciting alternatives for extending this transduction RTP approach to other analytical applications (particularly for luminescence optosensing). For example, Erythrosine B immobilized onto sol-gel materials proved to be an excellent RTP sensor for oxygen in nonaqueous media. Taking advantage of the fact that oxygen quenches this RTP emission very efficiently, a flow-cell-type sensing device can be used in SS-RTP optosensing of oxygen

**Figure 4** Flow injection setup for RTP optosensing of nafcillin using a molecularly imprinted sol-gel material as molecular recognition element.

in organic solvents using a simple flow setup as well as in gas mixtures (using a special flow manifold). These approaches hold promise for novel biosensing in oxygen-mediated biochemical reactions both in organic solvents (e.g., cholesterol determination) and at the solid–gas interface (e.g., ethanol or methanol vapor determinations). The applicability and convenience of use (easy automation) of the SS-RTP optosensing approach should encourage active research in this field in the future for the development of new (bio)chemical sensors. Analytical data for RTP oxygen determination in different scenarios are shown in Table 2.

Another application of particular note involving SS-RTP is the technology named phosphorescence barometry, which provides an inexpensive method for continuous pressure mapping of aerodynamic and automotive surfaces. The technology makes use of a luminescent paint (pressure-sensitive paint) that consists of an oxygen permeable polymer (e.g., silicone resins) in which a phosphorescent compound, a platinum porphyrin derivative, is dispersed. A temperature-sensitive paint would be similar except that an oxygen impermeable support should be used (e.g., an epoxy resin).

In this approach, pressure sensitivity is based on the oxygen quenching of the RTP of the dispersed platinum porphyrin complex. In practice, the surface

to be studied is coated with the paint and illuminated with light of the appropriate energy to excite the coating-entrapped probe molecules. The luminescence intensity is found to be proportional to the pressure at the surface as air contains a constant fraction of oxygen, independent of the total pressure. RTP images are captured with a charge-coupled device (CCD) camera with computer interface (Figure 5). Calibration is accomplished by obtaining a reference image (wind tunnel fans off,  $I_{\text{ref}}$ ) for which the pressure distribution is constant and equal to atmospheric conditions. In the run conditions (wind-on,  $I$ ), the pressure distribution is unknown:

$$\frac{I_{\text{ref}}}{I} = A + B \frac{P}{P_{\text{ref}}} = A + B \frac{\tau_{\text{ref}}}{\tau}$$

The coefficients  $A$  and  $B$ , which are temperature dependent, are experimentally determined. Calibration of the intensity ratio ( $I_{\text{ref}}/I$ ) or lifetime ( $\tau$ ) can be correlated with the output of the CCD. The entire test object can be sampled simultaneously and the output of the array can be visually represented as an image with unequaled spatial resolution, thus providing a convenient tool for the generation of a spatially continuous pressure map. Compared to conventional pressure tap methods, RTP barometry does not require drilling holes in the studied surface,

**Table 2** Analytical figures for RTP oxygen sensing in different environments

RTP sensing phase	Dye immobilization	Medium	DL ( $\mu\text{g ml}^{-1}$ )	RSD%
EB-Sol-gel	Doped	Gaseous	6.0	0.06
		Aqueous	0.004	0.3
		Organic (hexane/chloroform)	0.49	1.4

provides a much faster response, and allows to map the pressure over the entire surface. This technique is currently being applied to the challenging problem of insect flight.

## Room-Temperature Phosphorescence in Microcrystalline/Colloidal Media

A microcrystalline or a colloidal-like suspension generated by syringe injection of a dilute organic solution of a PAH into pure water fulfils all the criteria for colloidal dispersion, except that the particles are larger. In this crystalline state, molecular diffusion is negligible and intermolecular photophysical events depend upon the crystal-formation step. A major spectral feature observed for many colloidal PAHs is intense RTP. This phenomenon is quite similar to SS-RTP. Generally, all colloidal RTP spectra exhibit large blue shifts compared to cryogenic temperature conditions, while the spectral resolution is much better than in MS-RTP spectra and only slightly worse than in low-temperature phosphorescence. It should be noted that colloidal RTP is completely insensitive to oxygen quenching. These features are observed in RTP spectra of fluorene, naphthalene, dibenzofuran, biphenyl, and others PAHs. However, the analytical potential of this technique is rather limited.

## Introduction

Phosphorus in the hydrosphere may originate from natural diffuse sources such as the weathering of phosphate minerals, the decay of algae, plants, runoff from grazing and agricultural land, or it may be derived from anthropogenic point sources such as sewage and industrial effluent discharges. Phosphorus

plays a critical role in the process of eutrophication, because in many aquatic systems it is the nutrient that limits the growth of phytoplankton.

Phosphorus occurs in a variety of physically and functionally different inorganic and organic forms in aquatic systems (**Figure 1**). An understanding of these forms is important because it is the speciation that controls their physical and chemical behavior and their biological availability.

The simplest definition of phosphorus species involves separation of the dissolved and particulate components of a sample by filtration (**Figure 1**). The dissolved component is operationally defined by the filter pore size; for this reason, the term 'filterable' is

provides a much faster response, and allows to map the pressure over the entire surface. This technique is currently being applied to the challenging problem of insect flight.

## Room-Temperature Phosphorescence in Microcrystalline/Colloidal Media

A microcrystalline or a colloidal-like suspension generated by syringe injection of a dilute organic solution of a PAH into pure water fulfils all the criteria for colloidal dispersion, except that the particles are larger. In this crystalline state, molecular diffusion is negligible and intermolecular photophysical events depend upon the crystal-formation step. A major spectral feature observed for many colloidal PAHs is intense RTP. This phenomenon is quite similar to SS-RTP. Generally, all colloidal RTP spectra exhibit large blue shifts compared to cryogenic temperature conditions, while the spectral resolution is much better than in MS-RTP spectra and only slightly worse than in low-temperature phosphorescence. It should be noted that colloidal RTP is completely insensitive to oxygen quenching. These features are observed in RTP spectra of fluorene, naphthalene, dibenzofuran, biphenyl, and others PAHs. However, the analytical potential of this technique is rather limited.

## Introduction

Phosphorus in the hydrosphere may originate from natural diffuse sources such as the weathering of phosphate minerals, the decay of algae, plants, runoff from grazing and agricultural land, or it may be derived from anthropogenic point sources such as sewage and industrial effluent discharges. Phosphorus

plays a critical role in the process of eutrophication, because in many aquatic systems it is the nutrient that limits the growth of phytoplankton.

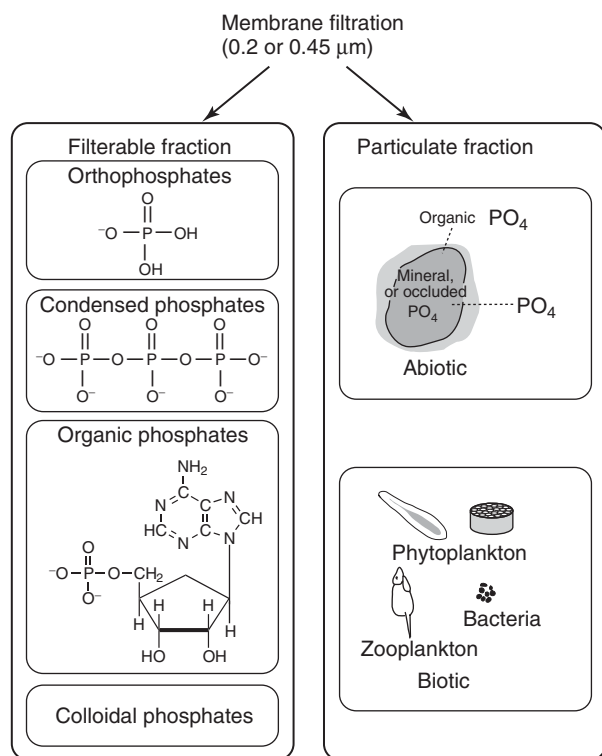

Phosphorus occurs in a variety of physically and functionally different inorganic and organic forms in aquatic systems (**Figure 1**). An understanding of these forms is important because it is the speciation that controls their physical and chemical behavior and their biological availability.

The simplest definition of phosphorus species involves separation of the dissolved and particulate components of a sample by filtration (**Figure 1**). The dissolved component is operationally defined by the filter pore size; for this reason, the term 'filterable' is

preferred to either 'dissolved' or 'soluble', both of which are used extensively and interchangeably in the literature. The filterable total phosphorus (FTP) component is comprised of the filterable reactive (FRP), condensed (FCP), and organic (FOP), fractions. Of these, the FRP consists of inorganic orthophosphates ( $\text{H}_2\text{PO}_4^-$ ,  $\text{HPO}_4^{2-}$ ,  $\text{PO}_4^{3-}$ ) and some labile organic and colloidal phosphates that will react with acidic molybdate to form the phosphomolybdate complex that is the basis for most phosphorus analysis. FCP consists of inorganic polyphosphates, metaphosphates, and branched ring structures, and the

FOP fraction is composed of compounds such as nucleic acids, phospholipids, inositol phosphates, phosphoamides, phosphoproteins, sugar phosphates, aminophosphonic acids, phosphorus-containing pesticides, and organic condensed phosphates.

The particulate phosphorus (PP) fraction refers to the fraction retained by the filter (usually 0.45 or 0.2  $\mu\text{m}$  pore size membrane). PP may consist of biological material (animal, plant, bacterial), weathering products (primary and secondary minerals), precipitates (authigenic minerals), organic and inorganic coprecipitates and aggregates, in addition to phosphorus associated with aggregates through metal binding or adsorbed to the surface of clay and mineral particles. Determination of FTP, FOP, FCP, and PP in natural waters requires a preliminary digestion step to convert the various phosphorus species to the detectable orthophosphate form (Table 1).

**Figure 1** Representation of phosphorus species in aquatic systems operationally defined by filtration. (McKelvie ID, Peat D, and Worsfold PJ (1995) Techniques for the quantification and speciation of phosphorus in natural waters. *Analytical Proceedings* 32: 437–445; reproduced by permission of The Royal Society of Chemistry.)

## Spectrophotometric Detection

The analysis of phosphorus in waters has historically been based on the photometric measurement of 12-phosphomolybdate or the phosphomolybdenum blue species, which are produced when phosphomolybdate is reduced. The majority of manual and automated methods of phosphate determination are based on the spectrophotometric determination of phosphorus as phosphomolybdenum blue, i.e.,

followed by

Phosphorus species that are determined in this manner are referred to as molybdate reactive, or simply reactive, and much of the nomenclature of phosphorus speciation derives from this origin.

There have been numerous variations on this method, usually involving different reductants (tin(II) chloride, ascorbic acid, 1-amino-2-naphthol-4-sulfonic

**Table 1** Specification scheme for phosphorus (P) based on determination of molybdate reactive (R), phosphorus in total (T), filterable (F), and particulate (P) forms; O and C designate organic and condensed forms, respectively

	Total sample (T)	Filterable fraction (F)	Particulate fraction (P)
Total P determination: digestion + colorimetry	TP (TOP+TCP+TRP)	– FTP (FOP+FCP+FRP)	= PTP (POP+PCP+PRP)
Condensed P determination: hydrolysis + colorimetry	TCP+TRP	– FCP+FRP	= PCP+PRP
Organic P determination (by subtraction)	TOP	– FOP	= POP
Colorimetry (reaction with molybdate)	TRP	– FRP	= PRP

acid, sodium sulfite, hydrazine sulfate, or combinations thereof) or different acid concentrations, in attempts to improve the selectivity and stability of the chromophore produced. The most commonly used methods for both manual and automated analyses are based on the ascorbic acid reduction with potassium antimonyl tartrate as a catalyst, which is used because it is more tolerant of temperature and salinity variations, and is less susceptible to interference from silica.

## Speciation of Phosphorus Based on Digestion and Molybdate Reactivity

Major differences in size (filterable, particulate) and chemical reactivity (condensed, organic) of phosphorus forms in samples can be used as the basis for speciation, as shown in Table 1. Of these fractions, total phosphorus (TP) and FRP are perhaps the most commonly measured, although it is arguable that the understanding of the aquatic phosphorus cycle is somewhat lopsided because of that bias. For example, wastewater discharge licenses often specify a maximum permissible concentration of TP, and provide an indication of the maximum potentially bioavailable phosphorus discharged. However, FRP, comprising mostly orthophosphate, is a measure of the amount of most readily bioavailable phosphorus.

The determination of TP, condensed and organic phosphorus all require predigestion and/or hydrolysis of the water sample prior to detection of the orthophosphate produced. Complete conversion of particulate and filterable components requires conditions that are conducive to dissolution of phosphate mineral phases, hydrolysis of condensed phosphates, and oxidation of organic phosphorus species. Numerous methods have been proposed, but whichever procedure is selected for the determination of TP or FTP, the digestion efficiency should be assessed using appropriate certified reference materials and a range of organic or condensed phosphorus model compounds. The latter should include compounds such as tripolyphosphate, inositol hexakisphosphate, and 2-aminoethylphosphonic acid that contain P–O–P, C–O–P, or C–P chemical bonds, respectively, and that are known to be more refractory.

## Condensed Phosphorus Hydrolysis

Determination of the condensed phosphorus component requires hydrolytic conditions without oxidation, and is typically achieved by boiling samples with 0.05 M sulfuric acid for 90 min or autoclaving for 30 min, prior to determination as molybdate reactive phosphorus.

## TP Digestion

### Thermal Digestion Methods

Wet chemical digestions with either alkaline or acid peroxydisulfate are the most common digestion methods for determining TP. If the alkaline peroxydisulfate digestion is used, sufficient time must be allowed for complete breakdown of peroxydisulfate to sulfuric acid if the condensed component is to be hydrolyzed. Similarly, if nitric–sulfuric acid or nitric–sulfuric–perchloric acid is used, it must be established that the conditions used are sufficiently oxidizing to digest the most refractory organic compounds, like aminoethyl phosphonates. Digestion may be performed at ambient pressure, or, for greater speed, at elevated pressure and temperature using a pressure cooker or autoclave. Recovery tests for autoclave methods involving peroxydisulfate and nitric–sulfuric acid digestion reagents for determination of TP in waters with high suspended load have shown that recovery of TP at  $>100 \mu\text{g P l}^{-1}$  is incomplete using the peroxydisulfate reagent. Dilution to  $\leq 100 \mu\text{g P l}^{-1}$  is recommended to overcome this problem.

A number of workers have also reported the use of microwave ovens for thermal digestion of samples for TP analysis. Digestion times can be reduced significantly by the use of microwave heating, which can be performed both in batch and online flow injection modes.

As alternatives to the wet chemical methods described above, high-temperature combustion with magnesium sulfate followed by acid leaching or high-temperature fusion with magnesium nitrate have been proposed. The latter method has been shown to decompose phosphonates that are quite refractory.

### Photochemical Methods

Ultraviolet (UV) photooxidation may be employed to convert organic phosphorus to phosphate prior to detection, and can be performed either in batch mode using a high-intensity, ventilated UV source and a quartz reactor vessel, or in continuous-flow mode using either quartz or polytetrafluoroethylene (PTFE) photoreactors. Because batch UV radiation systems usually involve the use of high wattage UV lamps (e.g., 1000 W) and extended irradiation times, condensed phosphates are hydrolyzed due to the elevated temperature and gradual acidification of the sample as peroxydisulfate degrades to form sulfuric acid. Thus, UV photooxidation alone is insufficient to convert condensed phosphates to orthophosphate, and the use of UV photooxidation with alkaline peroxydisulfate may provide a basis for discrimination

between the organic and condensed phosphorus fractions.

Photooxidation of organic phosphorus may be performed by UV irradiation on the untreated sample, and relying on the dissolved oxygen present in the sample to provide an adequate source of oxygen or hydroxyl radicals. However, it is more common that hydrogen peroxide, peroxydisulfate, ozone, or other oxidizing agents are added to enhance the completeness of the oxidation process.

When  $\text{H}_2\text{O}_2$  is exposed to UV light, it forms hydroxyl radicals:

This radical is among the strongest oxidizing agents found in aqueous systems and initiates a series of radical chain reactions with organic substances, resulting in mineralization of the sample to bicarbonate and orthophosphate.

Photooxidation using peroxydisulfate also produces hydroxyl radicals and oxygen by the following route:

Titanium dioxide-mediated oxidation of organic phosphorus can also be achieved using long-wavelength UV. Excitation of an electron from the valence band (v) into the conduction band (c) creates an electron-hole pair, which may then react with, for example, oxygen adsorbed to the  $\text{TiO}_2$  surface to produce radicals such as  $\text{O}_2^-$  and  $\text{OH}^\bullet$ .

In order to determine the TP concentration in water, the digestion process must involve both oxidative and hydrolytic processes in order to hydrolyze P–O–P linkages (e.g., polyphosphates) and oxidize phosphoesters and C–P compounds to inorganic phosphate. For example, in an online TP digestion system, which involves both thermal digestion and UV photooxidation, it is necessary to use a mixture of sulfuric acid and peroxydisulfate in order to obtain high recoveries of both organic and condensed phosphorus.

## Bioavailable Phosphorus

Analysis of phosphorus species in natural waters is driven largely by a need to assess the likely potential for eutrophication, and a number of phosphorus

analysis parameters have been employed as estimators of bioavailable phosphorus (BAP).

### Algal Bioassay

BAP has traditionally been determined using algal bioassays (e.g., the algal assay bottle test). However, these take 7–21 days to perform, are labor intensive because they require daily measurement of the growth rate, are susceptible to large statistical variability, and are relatively insensitive. Furthermore, caution should be exercised in the interpretation of the BAP concentration obtained, because native algae may have a much wider range of phosphorus substrate activity than the axenic algal monocultures that are used for this purpose. Consequently, there has been a great deal of research effort into replacing algal bioassay by some chemical parameter that will provide a rapid and more convenient means of determining the BAP concentration.

### TP and FRP

Because of the time and labor involved in algal assays, FRP (0.45 or 0.2  $\mu\text{m}$ ) has often been used as a surrogate for readily BAP, and TP (which includes the particulate, condensed, and organic phosphorus components) as a measure of potentially BAP. However, a number of studies have shown that neither FRP nor TP correlate well with algal assay-measured BAP. This may be because FRP tends to overestimate the true orthophosphate due to hydrolysis of labile organic and condensed species. Use of ultrafiltration through a low molecular mass filter prior to measurement of reactive phosphorus has been proposed as better estimator of BAP than other available chemical methods.

### Iron Strip and DGT Methods

A proposed alternative for estimating the amount of BAP in waters involves the use of iron strip adsorption techniques used in soil science to measure plant-available phosphorus. This approach involves the equilibration of dissolved and particulate-bound phosphorus with an iron-oxide-impregnated paper strip for a period of hours to days, and this is followed by acid leaching and spectrophotometric analysis for FRP. These exchangeable phosphorus tests have been shown to be well correlated with BAP determined by algal bioassay in waters. However, co-adsorbed organic phosphorus or adsorbed particulate material may also be hydrolyzed at the iron-oxide surface and during the acid leaching and colorimetry stages of the process, leading to an overestimation of the amount of BAP.

**Figure 2** Representation of a steady-state concentration gradient in a DGT device.  $\Delta g$  is the thickness of the ion-permeable gel membrane,  $\delta$  is the thickness of the diffusive boundary layer, and  $C$  is the concentration of reactive phosphorus species in the bulk of solution. (Adapted from Zhang H, Davison W, Gadi R, and Kobayashi T (1998) *In-situ* measurement of dissolved phosphorus in natural waters using DGT. *Analytica Chimica Acta* 370: 29–38, with permission from Elsevier.)

An alternative approach is the use of diffusive gradients in thin films (DGT). Phosphate diffuses through a thin polyacrylamide gel and is bound in a second gel layer containing iron-oxide. *In situ* deployment is followed by sectioning, leaching, and analysis for molybdate reactive phosphorus. From a knowledge of the diffusion coefficient of phosphate in the gel and the measured phosphate concentration, the bulk solution phosphate concentration can be calculated from Fick's first law of diffusion (Figure 2). This enables a time-integrated measurement of FRP concentration, and can also be used to determine sediment–water fluxes of phosphate.

## Enzymatic Methods

Algae and bacteria are known to release extracellular alkaline phosphatase, which facilitates utilization of otherwise unavailable dissolved and particulate organic phosphorus species. This behavior has been used as the basis for a speciation technique aimed at estimating BAP in the dissolved fraction. Alkaline phosphatase has been used in soluble and immobilized forms to hydrolyze FOP in natural waters, and the resultant orthophosphate is detected as FRP. Use of the soluble enzyme technique has essentially been discarded because of product inhibition of the alkaline phosphatase by orthophosphate already present

in the water. However, if an immobilized alkaline phosphatase reactor is used in a flow injection configuration, the problem is obviated because the hydrolysis product is transported away from the active sites of the enzyme. The technique has been successfully applied to the determination of alkaline phosphatase hydrolyzable phosphorus (APHP) in a range of natural and wastewaters. The enzyme phytase has also been used in a similar manner to hydrolyze organic phosphates in waters. The use of these enzyme techniques thus provides additional information as to the functionality of the phosphorus species present.

## Selective Extraction Techniques for Phosphorus in Sediments and Soils

In soils and sediments, chemical fractionation or sequential extraction methods offer another approach to speciation of the forms of phosphorus. Traditionally, there has been more emphasis on bioavailable or plant available inorganic forms, e.g., Olsen's extraction used for soils.

The SEDEX procedure has emerged as the benchmark extraction scheme for sediments. It uses only magnesium chloride, acetate buffer, and citrate/dithionite–bicarbonate reagents at pH values between 4 and 8 to leach sediments of the inorganic associated phosphorus fractions before ashing at 550°C and a final extraction with 1 M HCl to determine the so-called residual organic phosphorus.

However, extraction of organic phosphorus from sediments and soils should be carried out in a manner that, as far as possible, avoids hydrolysis or oxidation to orthophosphate, and this is often incompatible with the procedures used for inorganic phosphorus extraction. Some authors have suggested that strongly acidic and basic conditions are intrinsically unsuitable for extraction because of the likely hydrolytic breakdown that they cause, and have suggested instead that chelating extractants such as NTA or ethylenediamine tetraacetic acid (EDTA) at near-neutral pH should be used as an alternative (Table 2).

## Determination of Specific Phosphorus Compounds

### Chromatographic Methods

**High-performance liquid and ion chromatography** Phosphate is commonly determined by ion chromatography, both in suppressed and unsuppressed modes. The sensitivity of the conductivity detection techniques commonly used may be inadequate for direct application to the analysis of pristine waters,

**Table 2** Sequential chemical extraction for isolation of various phosphate fractions involving use of chelating agents at near-neutral pH

Fraction designation	Abbreviation	Extractant used
Iron-bound phosphate	$\text{Fe}(\text{OOH}) \approx \text{P}$	0.02 M Ca-NTA/dithionite, pH 7.8–8.0
Calcium-bound phosphate	$\text{CaCO}_3 \approx \text{P}$	0.05 M Na-EDTA, pH ~8.0
Acid-soluble organic phosphate	ASOP	0.5 M HCl or 0.025 M $\text{H}_2\text{SO}_4$ (30 min)
NaOH-extractible phosphate	$\text{NaOH}_{\text{extr}}\text{-P}$	2.0 M NaOH (90°C, 30 min)

**Figure 3** (A) Ion-exchange chromatography–FIA system for separation of polyphosphates. (B) Optimized separation of orthophosphate ( $50 \mu\text{g PI}^{-1}$ ), diphosphate ( $50 \mu\text{g PI}^{-1}$ ), and triphosphate ( $50 \mu\text{g PI}^{-1}$ ) with an injection volume of  $500 \mu\text{l}$ . (Halliwell DJ, McKelvie ID, Hart BT, and Dunhill RH (1996) Separation and detection of condensed phosphates in waste waters by ion chromatography coupled with flow injection. *Analyst* (Cambridge, UK) 121: 1089–1093; reproduced by permission of The Royal Society of Chemistry.)

and some form of preconcentration is required. For analysis of seawaters, extensive dilution or chloride removal is necessary. The advantage of this technique is that it is true orthophosphate rather than FRP that is determined.

Anion exchange chromatography and ion exchange chromatography have been used extensively for the separation and quantitation of condensed phosphates. Because phosphate is a poor UV chromophore, direct UV detection cannot be used, and fraction collection for subsequent acid hydrolysis and detection as molybdate reactive phosphorus (MRP)

has been the norm. High-performance liquid chromatography (HPLC)-ion chromatography with post-separation hydrolysis and detection using flow injection analysis has advantages of speed of analysis, sensitivity, and selectivity. A schematic diagram of this instrument setup and typical separations obtained from a hyphenated system of this type is shown in **Figure 3**.

Interest in characterization of organic phosphorus present in natural waters has also prompted the development of ion chromatographic separation systems for compounds such as inositol phosphates.

Online UV photooxidation has been utilized for oxidation and subsequent detection of these organic phosphate species. While ion exchange HPLC is used extensively for separation of FOP species, a reversed-phase partition HPLC has a definite role in the separation of even quite charged or polar organic phosphorus species. Phospholipids are commonly separated and quantified using either reversed- or normal-phase HPLC. Reversed-phase HPLC has also been used in the study of inositol phosphates. Use of ion-pair reversed-phase HPLC is also advantageous for the separation of highly charged species and may avoid some of the adsorption problems that are encountered using gel filtration or ion exchange chromatography, especially of highly charged species. Reversed-phase ion-pair chromatographic separations have been described for inositol phosphates, and some common nucleotides and sugar phosphate phytate.

**Gel filtration/size exclusion chromatography** Separation using gel filtration gained popularity as a means of separating high and low molecular mass phosphorus fractions, and as a means of estimating BAP concentrations, i.e., the reactive low molecular mass phosphorus. Most involve the use of large separation columns, long elution times, and the use of fraction collection and off-line digestion/digestion to measure total or reactive phosphorus, and as such are unsuitable for routine monitoring applications. However, an on-line postcolumn flow injection detection system for detection of organic phosphorus species has also been described. Potential difficulties associated with the use of gel filtration include early elution due to anion exclusion and late elution due to hydrophobic interactions, and specific adsorption.

### Capillary Electrophoresis

Capillary electrophoresis (CE) techniques have been used for selective orthophosphate analysis. CE separations of anions in waters are much faster than ion chromatography, but detection of phosphate by UV absorbance is very insensitive. This may be overcome by on-capillary preconcentration using isotachopheresis, which enables  $\text{sub-}\mu\text{g l}^{-1}$  detection limits to be achieved in high ionic strength matrices.

### Gas Chromatography

Gas chromatography (GC) with either flame photometric or mass spectrometric detection is commonly used for determination of organophosphate pesticide. In some cases, GC may be used for separation of organic phosphorus species if they or their degradation products are derivatized, e.g., inositol

phosphates have been characterized by GC separation of their acetylated dephosphorylation products.

### Other Spectroscopic Methods

Nuclear magnetic resonance, especially  $^{31}\text{P}$  NMR, offers a powerful means of characterizing and identifying individual phosphorus species in soils and sediments. In the case of waters, there is usually the need for preconcentration, and interferences may arise because of the corresponding increase in concentration of paramagnetic substances. However, if these difficulties are resolved,  $^{31}\text{P}$  NMR provides a qualitative means of detecting the presence of functionally different phosphorus groups, such as phosphonates, orthophosphates, orthophosphate mono- and diesters, and pyrophosphates, within a sample.

GC–Mass spectrometry combines high-efficiency separation with sensitive and highly selective detection, and is a powerful tool for characterization of organic phosphorus.

## Introduction

In this article, the key principles of photoacoustic spectrometry (PAS) will be described together with a simple discussion of the instrumentation required to perform PAS. Some important applications will be discussed and future scope of the technique's application outlined. The introduction brings together some historical generalities of the technique followed by sections on its theoretical aspects, instrumentation, and analytical applications. The emphasis is on chemical analysis throughout.

Photoacoustic detection is one of a class of photothermal detection techniques that can be used to measure the optical absorption of a sample by monitoring the absorption of modulated ultraviolet (UV)/visible or infrared radiation and its subsequent conversion to heat by nonradiative processes to produce a periodic thermal signal. The signal is normally measured by the effect that the periodic heat flow has on the absorbing medium, i.e., the sample, or any medium in contact with the sample. For example, measurement of the change in refractive index that occurs on absorption of a modulated laser beam in a transparent or semitransparent medium is the basis of thermal lens detection, photothermal interferometry, and photothermal refraction. The use of these detection techniques and quantitation of absorption at different excitation wavelengths gives rise to photothermal spectrometry.

Most of these photothermal techniques, including PAS, have been exploited in the last 30 years for materials characterization and chemical analysis. However, the fundamental phenomenon of the photoacoustic effect was first observed by Alexander Graham Bell in 1880, who noted that when modulated sunlight was allowed to fall on absorbing materials in a transparent tube, sound was heard and that the more strongly absorbing materials produced louder sounds. This led to the construction of Bell's photo-phone. The principles by which sound was produced were later quantified and utilized by Rose-ncwaig and Gershov, and Kirkbright and Adams to provide a powerful new class of spectroscopic techniques originally known as optoacoustic spectrometry but now known as photoacoustic spectrometry or PAS.

In classical PAS, as demonstrated by Kirkbright and Adams, modulated continuum radiation from a high-power UV/visible continuum light source such as a high-pressure Xe or Hg lamp is passed through a monochromator to isolate particular wavelength bands. Monochromatic light thus selected then falls upon a gas-tight cell that contains the sample, and in the gas space above the sample, a sensitive microphone. The output of the microphone can be recorded as amplitude or connected to a phase-sensitive lock-in amplifier.

If the sample absorbs at the incident wavelength excitation takes place and subsequent relaxation of excited states via nonradiative mechanisms, such as collisional relaxation, generates heat. As the incident radiation is modulated the sample becomes periodically heated, which results in a periodic thermal wave propagating through the sample. When this periodic heat flow reaches the surface of the sample it propagates through the contacting gas as an acoustic wave, caused by the compression and rarefaction of the gas, which can be detected as sound by the microphone. It follows that the higher the absorption coefficient at the incident wavelength then the louder (higher amplitude) the signal. If the monochromator is a wavelength-scanning device then a complete optical absorption spectrum in the range of the spectrometer can be obtained simply by measuring the PAS signal at each wavelength. A great advantage of measuring the absorption spectrum in this way is that solid phases can be measured directly even if there are irregularities present that causes scattering at the surface. Thus, the analysis of powders and solids becomes feasible, which would not be when using conventional transmission spectrometry because of variable scattering.

Other information is also available when studying samples using PAS that derives from the processes of optical absorption and heat generation in the surface layers of the sample. For example, under certain conditions the depth from which a thermal signal can be detected in a sample depends upon the inverse of the modulation frequency. Thus, by changing the modulation frequency depth profiling can be achieved. Alternatively, depth information can be obtained by measuring the phase lag of the signal determined using lock-in detection. This dependency on modulation frequency is particularly important when using Fourier transform infrared (FTIR) spectrometers in conjunction with PAS cells to obtain IR spectra of solids because in FTIR each

wavelength is modulated in the interferometer output beam at a different frequency thus allowing the recovery of comprehensive depth information. This can, of course, also be a complicating factor if the depth information is not required. Alternatively, step scanning can be employed to impose a fixed modulation frequency on the interferometer output beam thus maintaining a constant thermal diffusion length. The principles of PAS with special reference to FTIR PAS are described in the following section.

## Theory and Principles

### Basic Principles of PAS

PAS involves the analysis of acoustic waves, generated as a result of the absorption of modulated light. The acoustic waves are generated in the following manner:

1. Excitation of a sample by UV/IR light modulated at a frequency,  $f$ , increases the sample's internal energy. Providing luminescence or photochemical degradation does not occur, the internal energy is converted into heat by nonradiative deexcitation of the excited states.
2. The heat propagates from the region of absorption back toward the sample surface in the form of a thermal wave.
3. At the sample–boundary gas interface the thermal wave heats the adjacent boundary gas, which expands and contracts periodically, creating acoustic waves modulated at the same frequency as the incident radiation. (The gas within the photoacoustic cell is assumed to behave like a perfect gas, where temperature variations induce equivalent pressure variations.)
4. The acoustic waves propagate through the cell to a microphone, where they are detected and the acoustic signal is converted into an electrical signal. Ideally, the PAS signal is directly proportional to the intensity of the incident beam.

The amplitude of the PAS signal at any wavelength is dependent on the ability of the sample to absorb at that wavelength; therefore, the microphone output is equivalent to the absorbance spectrum of the sample. Only photons absorbed by the sample produce a photoacoustic signal; therefore, unlike transmission and reflectance techniques PAS is unaffected by scattering and can be used to analyze highly scattering materials, e.g., fine powders, crystalline and biological samples. Although PAS is unaffected by scatter signal loss does occur. A fraction of the incident beam is lost due to reflection at the sample surface during sample excitation. This quantity is dependent upon the sample under analysis. Additionally, on

propagation of the thermal wave from the sample to the boundary gas a large fraction of the thermal wave is reflected back into the sample. This loss greatly affects the magnitude of the photoacoustic signal.

In addition to the generation of a photoacoustic signal, excitation of a sample with modulated light induces a number of additional responses, for example, IR emission is produced and a refractive index gradient is generated within and above the sample. Each response can be used to analyze the sample. The response used, however, is dependent upon the sample and the environment it is in.

### Rosencwaig Gersho Theory (RG Theory)

Rosencwaig and Gersho published their 'Thermal Piston' theory describing photoacoustic generation in solids in 1976. Prior to this publication the photoacoustic effect was principally used to quantitatively estimate gas concentrations within mixtures. The RG theory, the first to describe the photoacoustic effect mathematically, led to the rediscovery and rapid development of the photoacoustic technique. It was developed by solving one-dimensional, thermal diffusion equations defining heat propagation within a sample, its gaseous surroundings, and its backing material, following the absorption of light. By assuming the pressure at the sample surface to be dependent on the periodic temperature variation at the sample–boundary gas interface, and the gas to respond adiabatically to the pressure, Rosencwaig and Gersho solved the thermal diffusion equations, using appropriate experimental boundary conditions, and defined equations for the amplitude and phase of the induced photoacoustic signal. Many modifications to the RG theory followed, for example, to account for signal generation in multilayered samples and three-dimensional systems. These modifications have resulted in the high development of the photoacoustic technique.

### Depth-Profiling Capabilities

When analyzing a sample using PAS spectroscopy, the depth beneath the surface from which a photoacoustic signal originates is dependent upon the interaction between the sample's optical absorption length,  $\mu_i$ , and thermal diffusion length,  $\mu_s$ .

The incident beam decays exponentially as it propagates through the sample following excitation at its surface. The optical absorption length,  $\mu_i = 1/\beta$ , where  $\beta$  is the optical absorption coefficient of the sample, defines the maximum depth the beam penetrates the sample. Thermal waves also decay exponentially as they propagate from the region of absorbance where they are generated, to the

sample surface. The thermal diffusion length, which defines the maximum depth from which a photoacoustic signal can be detected before significant dampening makes it undetectable, is defined by eqn [1]:

$$\mu_s = (\alpha/\pi f)^{1/2} \quad [1]$$

where  $\alpha$  is the thermal diffusivity of the sample and  $f$  the modulation frequency of the incident light.

The magnitude of the photoacoustic signal is directly proportional to the heat generated within this depth. The thermal diffusion length tends to range from several to over a hundred micrometers.

The interaction between the thermal diffusion length, optical absorption length, and sample thickness ( $l$ ) is used to describe the photoacoustic properties of a sample. Thus, a sample is described as opaque if the optical absorption length is less than the sample thickness, and light cannot be transmitted through the sample. However, when  $\mu_l$  and  $\mu_s$  are greater than  $l$  the sample is described as optically and thermally thin, respectively, and when  $\mu_l$  and  $\mu_s$  are less than  $l$  the sample is described as optically and thermally thick, respectively.

The thermal diffusion length is dependent upon the modulation frequency of the incident radiation used during sample excitation (see eqn [1]). By changing the modulation frequency of the incident light the thermal diffusion length is varied, a property used to depth profile samples. The effect of modulation frequency on the depth from which a photoacoustic signal is detected, using a thermal diffusivity of  $0.12 \text{ cm}^2 \text{ s}^{-1}$ , is illustrated approximately in Figure 1. The depth-profiling capabilities of PAS have resulted in its frequent use in the structural determination of layered heterogeneous samples (transmission and reflection techniques do not provide

depth-related information, only the average over the thickness analyzed).

If PAS is to be used for its depth-profiling capabilities the thermal diffusion length must not exceed the optical absorption length of the sample. If  $\mu_l < \mu_s$  all incident radiation is absorbed within the thermal diffusion length, resulting in photoacoustic saturation of the signal. Photoacoustic saturation results in the truncation and broadening of spectral bands. Additionally, the sample acts as a blackbody making depth profiling impossible. For the photoacoustic spectrum to accurately represent the absorption spectrum the sample's optical absorption length must exceed the thermal diffusion length, a condition met by selecting the appropriate modulation frequency.

PAS does not require the incident beam to pass through the sample under analysis like conventional spectroscopic techniques; the depth probed is defined by the thermal diffusion length. By selecting an appropriate modulation frequency PAS can be used to analyze opaque solids. This is advantageous when compared to transmission techniques that require dilution before analysis can be performed.

## Instrumentation

The components essential to perform PAS spectroscopy are: a source that determines the PAS spectral range, a spectrometer or interferometer for wavelength selection, a method of modulation of the incident beam, and a photoacoustic cell.

### The Photoacoustic Cell

PAS is used to analyze solids, liquids, and gases with little or no sample preparation required. A simplified photoacoustic cell, used to analyze solids, is illustrated in Figure 2. This cell can also be used to analyze

**Figure 1** Effect of modulation frequency on thermal diffusion length.

**Figure 2** Diagram of a simplified photoacoustic cell.

liquids and gases. PAS tends to be used to analyze weakly absorbing, highly scattering or highly viscous liquids. These sample types are difficult to analyze by conventional techniques.

The photoacoustic cell consists of a small volumed, vibrationally isolated, closed chamber. The microphone that detects pressure changes within the cell chamber forms part of cell wall. The incident excitation beam enters the PAS cell via the window. The transmission range of this window defines the spectral range of the photoacoustic cell. When working in the IR region a KBr window is used. The greatest limitation of PAS is the background signal, generated by the cell window and walls absorbing the incident beam. By using optically transparent windows and polished cell walls this absorbance is reduced.

Following excitation and subsequent nonradiative de-excitation of the sample pressure waves are generated at the sample-boundary gas interface. These waves propagate through the gas-filled chamber to the acoustic microphone where they are detected and converted into an electrical signal. The gas through which the thermal waves travel must be nonabsorbing and transparent to the spectral range of interest. Usually air or helium is used. Helium is favored because its thermal coupling properties increase the sensitivity of the technique by two to three times, owing to its decreased heat capacity compared to air. Additionally, helium purging eliminates water and carbon dioxide, which, unless removed, are present in the resultant spectra. The ability to remove air and moisture allow the analysis of unstable samples in an inert atmosphere, an advantage over conventional spectroscopic methods.

When using the PAS cell illustrated in **Figure 2**, solids and liquids are simply placed in the sample cup. Spectral analysis of a gaseous compound is performed by filling the PAS cell with the gas. All spectra are normalized by division with a spectrum of carbon black, a procedure that removes spectral variations due to the source, optics, and detector.

Solids should be dried in an oven/desiccator prior to analysis to ensure no water is generated upon irradiation and the incident beam should be attenuated when analyzing liquids to reduce evaporation. These precautions are essential in FTIR-PAS because the KBr window is easily damaged by water and gaseous compounds condensing upon it. When analyzing solids, peak intensities can be dependent upon the particle size and packing density, with the PAS signal increasing as the particle size decreases, and the surface area increases.

Spectral analysis of a gaseous compound is performed by filling the PAS cell with the gas. A cylindrical

cell with windows at each end is favored for gas studies. The cell is filled with the gas and the incident beam passes directly through the cell. This system reduces reflections of the incident beam on the cell walls, which would occur when using the cell above, and affect the PAS signal. Photoacoustic signal generation in a gas varies slightly with solids and liquids. When analyzing solids and liquids the photoacoustic signal is detected indirectly by monitoring periodic changes in the boundary gas surrounding the sample. When analyzing gases the pressure variations are measured directly within the gas. The gas absorbs the modulated light upon excitation increasing its pressure, and the microphone detects the resulting pressure fluctuations that occur at the same frequency as the modulated incident light.

### Modulation of the Incident Beam

The incident beam must be modulated prior to photoacoustic excitation of the sample. When the beam is modulated it oscillates in intensity. Modulation of the beam is essential for the periodic production of the heat. Conventionally modulation is performed using a rotating sector (chopper) that interrupts the beam periodically, resulting in the periodic change of the pressure within the cell. Depth profiling is performed by changing the chopping frequency, and hence modulation frequency of the incident radiation. High chopping frequencies correspond to shallow depths and low frequencies correspond to depths deep within the sample. This method of modulation is successful but can introduce significant noise contributions to the PAS signal especially when probing shallow depths when high chopping frequencies are required. A chopper is often used to modulate the incident beam (amplitude modulation) when using a dispersive spectrometer for PAS studies. This can introduce additional problems because the PAS signal is directly proportional to the intensity of the beam, but dispersive instruments experience power loss at the input and exit slits reducing the incident beam intensity and the PAS signal.

Currently, in the IR region, modulation is performed using interferometric methods. The interferometer has a greater optical throughput, signal-to-noise ratio, resolution, speed, and spectral range, than the dispersive instrument. (The greater signal-to-noise ratio arises from the interferometer's multiplex and throughput advantages.) Consequently, by combining interferometry and photoacoustic spectroscopy, problems associated with the dispersive spectrometer and chopper setup are avoided, resulting in the significant development of the technique. Modulation by interferometry is the preferred method

for the majority of photoacoustic studies performed today.

An idealized Michelson interferometer is illustrated in **Figure 3**. The interferometer modulates the incident beam by changing the optical path difference of the interferometer. The optical path difference can be changed continuously or in increments, methods called rapid scanning and step scanning, respectively.

In 'rapid scan mode' the motion of the interferometer's moving mirror modulates the incident beam sinusoidally. The mirror travels at a constant velocity,  $v$ , along its trajectory, continuously varying the optical path difference, modulating the beam at a frequency  $f = 2v/\lambda$ , where  $\lambda$  is the wavelength of incident beam and  $v$  the velocity of the moving mirror. The modulation frequency is dependent upon wavenumber; therefore, as defined by eqn [1], the thermal diffusion length (PAS sampling depth) varies linearly across the spectral range, increasing with decreasing wavelength. This dependence of thermal diffusion length on modulation frequency can be used to depth profile materials.

In 'step scan mode' the optical path difference is changed incrementally, the mirror does not scan continuously. It steps to a position, collects data, and moves to the next position. Data are collected at each step with the path difference held constant. At each step the mirror is jittered at a constant frequency, a procedure that modulates the incident beam. The ability to select a constant modulation frequency, independent of the mirror velocity and wavenumber, results in a constant probed depth over the entire spectral range. This is advantageous over the varying sampling depth observed when using rapid scanning,

because it simplifies depth-profile analysis. Step scanning also permits the use of phase modulation techniques to obtain higher signal-to-noise ratios than can be obtained by amplitude (chopper) modulation.

## Applications of PAS

Since the early days of PAS two of its properties have been important in defining its role as a complementary technique to other molecular spectrometric techniques in the visible near-IR and IR regions of the electromagnetic spectrum. These are the freedom of effects of scattering particles, which derives from the fact that a thermal signal is measured via the acoustic wave rather than attenuation or reflection of an optical beam, and the depth-profiling capability as described in the previous section. Thus, the technique has proved extremely useful for making direct measurements of solid materials that would be rendered impossible by optical techniques because of their opacity. In addition, as the PAS technique utilizes measurement of an acoustic wave in gases it has also found a further limited use in atmospheric pollution measurements. There are few reviews available that describe applications of the technique, so in the remainder of this article we have selected a few recent publications for discussion to illustrate the range of applications of the PAS technique.

The predominant trend in recent years has been the growth of FTIR-PAS driven by the ease with which depth information can be obtained through either rapid scanning or step scanning/phase modulation techniques. The use of FTIR-PAS has also opened up the possibility of recording time-resolved depth measurements to facilitate chemical mass transport and diffusion studies, which is of particular interest for drug diffusion studies. For example, Nakamura *et al.* employed a rapid scanning technique and diffusion model to determine the diffusion coefficient of the angina prophylactic nitroglycerin from drug delivery patches through a skin mimetic. The model utilized four different IR wavelengths of the nitroglycerin IR-PAS spectrum to monitor its mass transport rate through the mimetic and to compute the diffusion coefficient. More recent work has refined this model and the diffusion rate thus determined has been shown to compare favorably with that obtained using attenuated total reflection (ATR) IR spectrometry. In a previously published paper Hahn *et al.* used step scan FTIR-PAS with phase modulation to determine penetration rates of dithranol and methoxsalen from a semisolid Vaseline<sup>®</sup> into an artificial dodecanol-collodion membrane by monitoring appropriate IR absorption bands of the active drugs in the formulation. The work

**Figure 3** Diagram of an idealized Michelson interferometer.

demonstrated that FTIR-PAS was most suitable for obtaining the drug penetration profile in the membrane whereas the ATR technique was favored for surface penetration measurements in accordance with the relative depths that can be probed with the techniques, PAS providing deeper measurement depths than ATR.

The depth-profiling capability of step-scan mode FTIR-PAS was also exploited in the measurement of coated papers by Halttunen *et al.* Coatings of cationized starch and sodium oleate (a surfactant) were characterized at depths of 20–60  $\mu\text{m}$ . The study, using a phase modulation technique, was able to demonstrate that the position of the surfactant carbonyl band is influenced by its chemical environment and the presence of the paper, and also that the surfactant is enriched in the outermost surface of the coating. This ability to discriminate chemical composition is perhaps one of the most significant uses to which PAS can be applied and is taken to its extreme in an elegant piece of work published by Jiang in which the microsampling capabilities of FTIR-PAS are explored. The technique was applied to single particles and fibers coated with oils, greases, and gels in order to determine their heterogeneity. Thus, depth information concerning oil-coated polymer beads of 150  $\mu\text{m}$  diameter and gel-coated human hair was obtained. The ability to study such discrete and small entities may well have significance in the drive to apply spectroscopic techniques to single biochemical cell analysis and Lab-on-a-chip applications. Fiber analysis has also been developed by Jurdana *et al.* in a study of nondestructive evaluation of keratin to determine spectroscopic differences between the cortex and cuticle of wool and hair fibers attribute to differences in protein composition between these domains. In that study both rapid and step scans were used to depth profile the samples.

Turning to gas analysis, there has been interest in the use of PAS to study systems of environmental importance. A particularly useful study has been published by Sigrist, who used a tuneable CO IR-laser PA system to study multicomponent gas mixtures, in particular volatile organic compounds in automobile exhaust systems. A separate CO<sub>2</sub> laser PAS system was also employed for air monitoring in urban and rural locations for the selective determination of species such as H<sub>2</sub>O, CO<sub>2</sub>, NH<sub>3</sub>, O<sub>3</sub>, and C<sub>2</sub>H<sub>2</sub> in the parts per billion to parts per million concentration range. Similarly, a CO<sub>2</sub> laser PAS system has been applied to the analysis of gas samples emitted by a diesel engine left running in a closed room, by Schramm *et al.* The species of interest, SO<sub>2</sub> and NO<sub>2</sub>, were detected in the parts per million range. The results demonstrated the importance of

considering the contribution of diesel exhaust from generating equipment to atmospheric pollution.

There are many other applications of PAS including the analysis of industrial samples not amenable to conventional spectroscopic analysis using UV/visible and IR spectrometry, especially those solid sample that are opaque. We have only outlined a few of the more interesting and as some would say academic examples of the use of PAS. However, this can be justified in pointing the way forward to the requirement for research in the analysis of specialist materials and in specialist scientific areas that require information that is difficult or tedious to achieve by conventional means. It is perhaps here that the niche for the still relatively uncommon technique of PAS will be best applied.

### Introduction

A plastic is a material that contains as a major component one or more organic polymeric substances of high molecular weight. It is a solid in its final state, and, at some stage in its manufacture or processing into final products, can be shaped by flow. One of the most important classes of materials in which plastics are contained is synthetic resins. These resins vary widely in their chemical composition and their physical properties. The number of synthetic resins that can be synthesized is large; however, relatively few have achieved commercial importance. Well over 90% of all synthetic resins made today comprise no more than 20 different types, although there are certain variations within each type. Plastics also have other uses (in the manufacture of surface coatings, glues, synthetic textile fibers, etc.).

Synthetic resins can be divided into two classes: thermosetting and thermoplastic resins, each class differing in its behavior on heating. Both types are composed of macromolecules; the difference in their

thermal behavior is due to differences in the structure of the resins. A thermoplastic polymer is capable of repeatedly being softened by heating and hardened by cooling through a characteristic temperature range and in the softened state can be shaped by flow into articles, mostly by injection molding or extrusion. A thermosetting polymer, having been cured by heat or other means, is substantially infusible and insoluble. The macromolecules of a thermosetting resin often consist of extensively branched chains that are chemically cross-linked, thus forming a complex network. On heating, there is less possibility of free movement, so that the material remains rigid.

Plastics can be divided according to their character into amorphous and crystalline. Crystallization is never complete and the so-called crystalline polymers are virtually semicrystalline ones. Examples of amorphous plastics are polystyrene, acrylonitrile–butadiene–styrene copolymers, styrene–acrylonitrile copolymers, polymethylmethacrylate, poly(vinyl chloride), cellulose acetates, phenylene oxide-based resins, polycarbonates, etc. Amorphous polymers are characterized by their glass transition temperature, semicrystalline polymers by both melting and glass transition temperatures.

Most commercially produced plastics are complex mixtures of many components, involving the

### Introduction

A plastic is a material that contains as a major component one or more organic polymeric substances of high molecular weight. It is a solid in its final state, and, at some stage in its manufacture or processing into final products, can be shaped by flow. One of the most important classes of materials in which plastics are contained is synthetic resins. These resins vary widely in their chemical composition and their physical properties. The number of synthetic resins that can be synthesized is large; however, relatively few have achieved commercial importance. Well over 90% of all synthetic resins made today comprise no more than 20 different types, although there are certain variations within each type. Plastics also have other uses (in the manufacture of surface coatings, glues, synthetic textile fibers, etc.).

Synthetic resins can be divided into two classes: thermosetting and thermoplastic resins, each class differing in its behavior on heating. Both types are composed of macromolecules; the difference in their

thermal behavior is due to differences in the structure of the resins. A thermoplastic polymer is capable of repeatedly being softened by heating and hardened by cooling through a characteristic temperature range and in the softened state can be shaped by flow into articles, mostly by injection molding or extrusion. A thermosetting polymer, having been cured by heat or other means, is substantially infusible and insoluble. The macromolecules of a thermosetting resin often consist of extensively branched chains that are chemically cross-linked, thus forming a complex network. On heating, there is less possibility of free movement, so that the material remains rigid.

Plastics can be divided according to their character into amorphous and crystalline. Crystallization is never complete and the so-called crystalline polymers are virtually semicrystalline ones. Examples of amorphous plastics are polystyrene, acrylonitrile–butadiene–styrene copolymers, styrene–acrylonitrile copolymers, polymethylmethacrylate, poly(vinyl chloride), cellulose acetates, phenylene oxide-based resins, polycarbonates, etc. Amorphous polymers are characterized by their glass transition temperature, semicrystalline polymers by both melting and glass transition temperatures.

Most commercially produced plastics are complex mixtures of many components, involving the

polymer matrix, oligomers, residual monomers, and additives, such as plasticizers, antioxidants, lubricants, and flame retarders. All these components determine the properties of plastics. The analysis of plastics is more complicated than other organic analyses. For example, functional group analysis is limited by the poor solubility of polymers and often their degradation products (pyrolytic or hydrolytic) must be investigated. Physicochemical methods, primarily spectroscopic, thermoanalytic, and chromatographic, make the analysis of plastics substantially easier.

## Analytical Techniques

Analysis of plastics is a complex task and involves preliminary tests, determination of nonmetallic and metallic elements, analysis of functional groups and double bonds, molecular weight determinations, chemical compositional analysis, sequence length distribution in copolymers, determination of tacticity and branching in polymers, and analysis of additives. Because of the great variety in structures in commercially produced plastics, the number of methods that can be applied for their analysis is considerable.

## Preliminary Tests

An unknown plastic from which additives or admixtures have been removed can be subjected to the following tests:

1. Evaluation of the plastic properties, e.g., coloration, tactile properties, smell, elasticity, hardness or fragility, transparency, translucence, etc. The manner in which the plastic is applied can also be revealing.
2. Flame tests (orientative) provide rough information on the test polymer.
3. Pyrolysis test. Thermoplastic and thermosetting polymers can be differentiated by this test.
4. Solubility test. Solubility in acetone, benzene, dimethylformamide, ethanol, chloroform, water, dioxan, acetic acid, acetates, formic acid, phenols, ethylene glycol, tetrahydrofuran, etc., is tested.
5. Chemical characteristics. These include hydroxyl and acid values and saponification values.
6. Physical characteristic. Melting temperatures  $T_m$  (melting ranges) and glass transition temperature  $T_g$  are characteristic constants of plastics and thus can be used for their identification and quality control. Table 1 lists  $T_g$  and  $T_m$  values for selected polymers.

**Table 1** Glass transition temperatures  $T_g$  and melting points  $T_m$  of selected polymers

Polymers	$T_g$ ( $^{\circ}\text{C}$ )	$T_m$ ( $^{\circ}\text{C}$ )
Polyacrylonitrile	100	320

## Determination of Metallic and Nonmetallic Elements

Polymers contain various elements, metallic and nonmetallic. Some elements are a constituent part of the monomers, such as nitrogen in acrylonitrile or chlorine in poly(vinyl chloride), while other elements occur as impurities or are part of some additives (e.g., zinc stearate). Their concentrations range from a  $\mu\text{g}$  per kg level to several percent. Analysis of the element content is especially important for manufacturing process control. Elements can be determined after chemical or physical destruction of polymer, or directly by nondestructive methods.

### Destructive Methods

**Dry ashing with or without ashing aid** This involves combustion of the polymer under controlled conditions in a platinum crucible (possibly with an ashing aid, e.g., magnesium carbonate, to prevent losses). The residue is then treated with dilute nitric acid or by fusion with potassium peroxodisulfate.

**Wet ashing with sulfuric acid** This is a very common technique. It involves oxidative degradation of plastic with sulfuric acid.

**Microwave-assisted digestion in a closed vessel** This method is based on degradation of plastic with

concentrated  $\text{HNO}_3/\text{HF}$  in a microwave furnace. This method gives the best results.

#### **Fusion with sodium carbonate or sodium peroxide**

The polymer is mixed with sodium carbonate or a mixture of sodium peroxide and sucrose or ethylene glycol, and ashed in a muffle furnace at  $500^\circ\text{C}$  (for sodium carbonate) or in an autoclave. The method is suitable for determination of zinc, chlorine, and bromine.

**Oxygen flask combustion** Combustion takes place at atmospheric pressure in oxygen; water is used as the absorbent. It is suitable for determining sulfur, phosphorus, chlorine, and bromine.

**Micro-Kjeldahl digestion method** The classical method has been adapted for determination of nitrogen in plastics.

**Atomic absorption spectrometry and atomic emission spectrometry** These are very useful techniques for determination of metals at low concentrations.

#### **Nondestructive Methods**

**X-ray fluorescence spectrometry** This technique is extensively used in the industrial analysis of plastics for routine determination of traces of metals and nonmetal elements, i.e., iron, cobalt, nickel, chromium, copper, zinc, chlorine, bromine, titanium, aluminum, sodium, potassium, calcium, magnesium, vanadium, cadmium, and selenium. The main advantages are simple sample preparation and independence on the element state in chemical combination.

**Neutron activation analysis** This is a very sensitive technique applicable to a wide range of elements present in plastics.

**Electron probe microanalysis and scanning electron microscopy** These are suitable techniques for identifying the nature of metallic inclusions in polymer films and sheets.

### **Determination of Molecular Weight**

Polymer consists of macromolecules with different chain lengths. The average molecular weight of a plastic, i.e., number average, mass average, and viscosity average, can be determined by osmometric, light scattering, and viscometric measurements and by mass spectrometry, respectively. Average molecular weight of plastics can also be calculated from the results of functional analysis of the end groups (i.e.,  $-\text{COOH}$ ,  $-\text{NH}_2$ ,  $-\text{SH}$ ,  $-\text{OH}$ ). The distribution of molecular weights in polymers can be determined firstly by size-exclusion chromatography (see below),

and also by solubility fractionation and turbidimetric titration.

### **Determination of the Structure of Plastics**

The functional groups and the degree of unsaturation are the main structural components to be determined in plastics. Functional groups and double bonds can be present in plastics, over a wide range of concentration, from a few  $\mu\text{g}$  per kg to several percent. On the basis of their determination, the polymer can be identified. Functional analysis of the end groups gives the average molecular weight of a plastic. Techniques for their determination can be divided into chemical and instrumental methods.

#### **Microchemical Methods**

Many of the techniques that are applicable to the determination of functional groups and double bonds in organic compounds are also applicable to polymers. Typical examples are:

- a titration procedure for the determination of carboxylic groups in acrylic copolymers;
- acetylation and phthalation procedures for determination of hydroxyl groups (determination of primary and secondary hydroxyl groups using reaction with toluenephenyl isocyanate and/or reaction with toluene diisocyanate, respectively);
- a saponification procedure for the determination of ester groups;
- derivatization methods, for example, the reaction of 2,4-dinitrophenylhydrazine with carbonyl groups present at low concentrations, followed by ultraviolet (UV)–visible spectrophotometry;
- iodine monochloride and bromination procedures for determination of the unsaturation degree (e.g., in styrene–butadiene copolymers and polymethylacrylate, respectively); and
- hydrogenation methods for total unsaturation in polymers.

#### **Instrumental Methods**

Spectral methods based on UV–visible spectrophotometry, laser-induced breakdown spectroscopy (LIBS), infrared (IR), Raman, nuclear magnetic resonance (NMR) spectroscopy, mass spectrometry (MS), thermoanalytical and chromatographic methods, especially liquid chromatography (LC) or gas chromatography (GC) combined with pyrolysis are most common.

## Spectroscopic Methods

**Ultraviolet spectrophotometry** This technique has been used extensively for polymers of the polystyrene or polyacrylate types. It has also been used for the estimation of optical properties of polymers (transparency, haze, color, and color stability) and quantitative analysis of additives (antioxidants, UV stabilizers, etc.).

**Infrared spectrometry** This spectrometry is one of the most frequently used methods in analysis of plastics. IR spectra in the region of up to  $4000\text{ cm}^{-1}$  are characteristic of the polymer. IR spectra of plastics can be measured by the thin-film, KBr-disc, or attenuated total reflectance (ATR) techniques. The ATR technique is very useful when normal transmission methods fail, e.g., for analyzing surfaces of elastomeric materials with low glass transition temperatures (polyethylene, polypropylene, poly(vinyl chloride), urethanes, polyester-melamine, and silicon-containing polymers), determining crystallinity, surface modification, and defect structures in materials. Fourier transform infrared (FTIR) spectrometers are well suited to all spectrometric purposes, especially to ATR and near-IR (NIR) techniques. Compared with dispersive IR spectrometers, they have a greater energy throughput, a higher resolution, a better wavelength calibration, and a higher signal-to-noise ratio. Hundreds of scans can be run and co-added in a few minutes. Plastics are identified on the basis of a comparison of measured IR spectra with computer-retrieved spectra of standard polymers (fingerprinting). Identity of a plastic can be confirmed by other methods, e.g., pyrolysis-gas chromatography. Near-IR spectroscopy has become widely used in analysis of plastics. The main reasons are that NIR instruments are generally easy to operate, results are obtained very fast, and there is little to no sample preparation required.

**Laser-induced breakdown spectroscopy** This is based on the emission spectrometry from the plume induced by a focused laser pulse. It enables both on-line and *in situ* trace determination of elements.

**Mass spectrometry** This is often used for analysis of plastics. Thermal degradation can be carried out using an ion source, or in a pyrolyzer connected directly to a mass spectrometer or via a chromatographic column. Two soft ionization techniques, electrospray ionization and matrix-assisted laser desorption ionization (MALDI), are the most common in the analyses of large molecules. MALDI-MS is usually used offline but online connection with a

separation method such as size-exclusion chromatography is possible. MS methods offer a very high resolution. They have been applied to the qualitative and quantitative analysis of plastics, oligomers, and additives. Search in a mass spectral library and pattern recognition analysis are usually employed for the identification of plastics. Information on number-average molecular weight, molecular weight distribution, end group composition, unsaturation, branching, etc., can be obtained by these techniques.

**Laser-induced mass analysis (LIMA)** This provides information on elements and various species in a single particle.

**Raman spectrometry** This is one of the nondestructive methods of polymer analysis; polymer samples can be measured directly, without any pretreatment. While Raman spectra primarily reveal the vibrations of the molecular skeleton (e.g., carbon atom chains), IR spectra are better suited for observing the vibrations of polar groups. An advantage of Raman spectrometry is the possibility of measurement over the whole wavelength range, from 5 to  $4000\text{ cm}^{-1}$ . Raman spectra provide information and limits of detection similar to those of IR spectra, but IR spectra are easier to obtain and cheaper. Therefore, Raman spectrometry is less common in industrial analyses of plastics.

**Nuclear magnetic resonance spectroscopy** NMR, especially  $^{13}\text{C}$  NMR, is well suited for structural analysis of polymers. It gives information on chemical compositional distribution, branching, and cross-linking in polymers and polymer tacticity. The sequence distribution in copolymers can be calculated from NMR data, e.g., for vinyl copolymers from chemical shift of the olefinic carbons of vinyl monomers. Heterogeneity, e.g., due to fluctuation in parameters involved in the reaction process during polymerization, can be followed by solid-state  $^{13}\text{C}$  and  $^3\text{H}$  NMR, expressed in terms of two-dimensional presentation. Curing of polymers can be followed by  $^2\text{H}$  NMR or  $^{13}\text{C}$  CP-MAS NMR. NMR has been extensively used for determination of degree of unsaturation and for functional analysis of carboxyl, ester, and carbonyl groups in plastics.

## Chromatographic Methods

After spectroscopic methods (IR, UV, NMR), chromatographic methods are the most suitable for separation, identification, and determination of plastics. They are used for determination of both volatile and

nonvolatile components, e.g., monomers, residual solvents, additives, oligomers, and polymer matrix.

**Gas chromatography** This is best suited for the analysis of volatile components, i.e., residual monomers and solvents. There are two possible methods:

1. headspace analysis; and
2. direct injection of a polymer solution or extract.

In headspace analysis, the plastic is placed in a vial (at a raised temperature) and the volatiles formed are stripped by a flow of carrier gas. The stripped volatiles are trapped in a suitable sorbent (e.g., using a solid-phase microextraction device) and subsequently thermally desorbed into a gas chromatograph. Process gas chromatographs are used in industrial analysis of volatiles in plastics. An example of this technique is the determination of residual vinyl chloride monomer in plastics in the range of 5–50 g per kg. With direct injection of a polymer solution, there is a danger of side-effects (a loss of reactive monomers due to polymerization in the injection port or an increase in its content due to depolymerization at a high injection temperature).

GC with thermostable stationary phases can be used for the analysis of substances with relatively high boiling temperatures. The possibilities of GC have been expanded using specific detectors, i.e., the electron-capture detector, alkali flame ionization detector, detection with an inductively coupled plasma, or by coupling GC with MS or FTIR (GC–MS or GC–FTIR). GC is also used for analysis of additives (slip agents, stabilizers, antioxidants) either directly or after conversion into volatile derivatives. It can also be utilized on a preparative scale for isolation of polymer additives for further identification, e.g., by using NMR. Inverse GC utilizes plastics as the GC stationary phases. The melting temperature, glass transition temperature, etc., can also be determined by this method.

**Thin-layer chromatography** This is often used for semiquantitative determination of stabilizers in plastics. The method is simple, cheap, easy to carry out, and can also be utilized for preparative purposes for identification by more sophisticated techniques (IR, NMR, MS).

**Liquid chromatography** This is a very efficient and versatile separation method. Depending on the separation mode (adsorption, separation on chemically bonded phases, or size exclusion), it can be used for analysis of stabilizers, monomers in polymers, oligomers, and high molecular weight polymers.

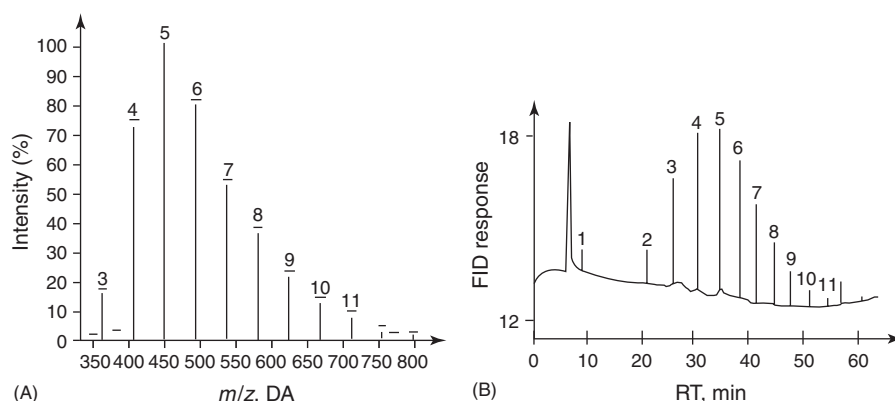

**Size-exclusion chromatography (SEC)** This is a powerful tool for evaluating size distributions in oligomers and polymers. The retention in SEC depends on the relative size of the solute molecules (Stokes radius) and the size and shape of the pores of the chromatographic stationary phase. Within an optimal linear separation range, the elution order is proportional to the molecular weight. In combination with UV photometric or refractive index detection, SEC is therefore suitable for determination of the relative molecular weight distribution of polymers; calibration with standard compounds is necessary. Depending on the size-exclusion limit of the stationary phase, either low molecular weight oligomers or high molecular weight polymers can be analyzed. Since the size of macromolecules may be affected by their composition and structure (e.g., long-chain branching), molecular-weight-sensitive detectors, e.g., low-angle or multi-angle laser light scattering detectors, viscometers, and MALDI-MS have been applied for the determination of absolute molecular weights. Several other detectors are useful in polymer analysis: diode-array UV detectors are important in determination of heterogeneity of copolymers and complex polymer systems; functional group distribution can be measured with an FTIR detector.

**Adsorption (liquid–solid) chromatography (LSC), normal- or reversed-phase liquid chromatography (NPLC, RPLC)** As polymers cannot be separated by SEC on the basis of their composition, other LC modes, e.g., LSC, NPLC, or RPLC, must be employed. Since the retention in these separation modes is proportional to the length of the polymer units, a gradient elution is necessary for polymer separation. Various detectors, similar to those applied in SEC, are used. High resolution can be obtained in RPLC. This is demonstrated in an example of separation of phenoxy polyethylene oxide oligomers (**Figure 1**). Analysis of oligomers is important for process control, as the oligomer's profile (oligomer formation, chain defects, and differences in the end groups) can be used in the modification of processing and synthesis procedures.

**Multidimensional chromatography** This combines two or more different separation modes in one experiment, e.g., SEC and RPLC, with different mobile phases, and is a very useful technique in analysis of polymers. The SEC column serves for a pre-separation step according to the molecular weight and the RPLC column then separates the substances in the fractions obtained from the SEC column according to their chemical composition. A scheme of the

**Figure 4** Thermal analysis of polypropylene (PP) and polyethylene (PE). Crystallinities, melting temperatures,  $T_m$ , and oxidation induction temperatures,  $T_o$ , are indicated. (Reproduced with permission from Widman G (1987) *Thermal analysis of plastics*. American Laboratory 19: 98–103.)

decomposed and the changes connected with the thermal degradation process are recorded by thermogravimetry (TG) or DSC. Often, differential thermogravimetry (DTG) curves are characteristic of certain plastics and can, therefore, be used for identification purposes. The behavior of plastics during oxidation is important for their practical use and for their recycling or environmental decomposition. The method permits the determination of melting temperature  $T_m$ , crystallinity, and the oxidation induction temperature as shown in **Figure 4**.

**Glass transition and melting behavior** Glass transition temperature  $T_g$  is an important parameter used for identification of plastics. The  $T_g$  value is the temperature at which amorphous polymers change from hard to soft. The concentration of crystalline regions in amorphous (semicrystalline) polymers affects the rigidity of the polymer. The crystalline melting

temperature  $T_m$  can be used for quality control and for identification of polymers. Glass transition temperatures ( $T_g$ ) and crystalline melting temperatures ( $T_m$ ) of selected polymers are listed in **Table 1**. Additives, solvent residues, moisture, etc. can lower the  $T_g$ , which is also influenced by the degree of curing; therefore,  $T_g$  allows the curing level to be monitored. Melting and softening processes are also influenced by the composition of copolymers and thus facilitate the determination of the composition of copolymers.

**Composition** The height of TG steps determines the quantity, while the temperature of DTG peaks determines the quality. Direct coupling of a thermal analyzer to a mass spectrometer enables the identification of degradation products, such as water, inorganic gases, volatile organic compounds.

**Curing reactions, degree of curing** Curing of thermosets can be monitored using thermoanalytical methods. Cross-linking and glass transition temperature,  $T_g$ , increase with increasing degree of curing. Differential photocalorimetry is a very effective method for process control, as both light and heat flow can be measured during curing.

## Analysis of Additives in Plastics

The properties of plastics are usually improved by adding different types of additives such as antioxidants, plasticizers (e.g., fatty acids, alcohols, esters, or hydrocarbons), UV stabilizers, flame retardants, slip agents, etc. Analytical problems arise from the following factors: the presence of additives in a more or less insoluble polymer matrix, the high reactivity of many types of additives, especially antioxidants, and the low concentrations of additives often present in the polymer matrix. Most methods for the

determination of additives in plastics fall in one of the following categories:

1. Analysis of compounds released upon heating the plastic (only applicable to volatile additives); gas chromatography is usually preferred.
2. Analysis of solvent extracts of plastics. Acetone, carbon disulfide, chloroform, cyclohexane, diethyl ether, ethanol, hexane, toluene, and water are used as solvents, extracts are further analyzed by, e.g., UV-visible spectrophotometry, fluorescence and phosphorescence methods, GC, LC, electrochemical methods, etc.
3. Direct examination of plastic, i.e., nondestructive testing of polymer films by IR or UV spectroscopy or of thicker sections of polymer by ATR IR spectroscopy to estimate antioxidants at levels ranging from 0.002% to 1.00%.

## Introduction

Polarography was first developed by Heyrovsky in 1922. The polarographic method was defined by the inventor as electrolysis with a polarizable dropping mercury electrode (DME) and it gained rapid acceptance not only in the investigation of electrode

processes but, particularly, as a very important analytical technique. In 1925, Heyrovsky and Shikata constructed the polarograph, a device that automatically records current–potential curves. The polarograph was probably the first automatic apparatus to be applied in analytical chemistry. The theoretical basis of the method was laid by Ilkovič in 1934 (the value of the diffusion current) and by Heyrovsky and Ilkovič in 1935 (the shape of the current–potential curve, i.e., the so-called polarogram).

Polarography uses potentiostatic control (Figure 1) of the working electrode polarized under conditions of convective diffusion; the current response  $i$  of the electrode system is measured depending on the polarizing voltage  $E$  whose time rate of change,  $dE/dt$ , is negligible with respect to the time constant of the mass transport toward the electrode surface. This means that measurable  $i$  is independent from the time rate of change of the polarizing voltage. The International Union of Pure and Applied Chemists definition limits polarography to the use of liquid electrodes whose surfaces are periodically or continuously renewed (e.g., dropping and streaming mercury electrodes).

Methods derived from polarography increase analytical sensitivity (or yield new information concerning the mechanism of the electrode process). Pulse polarographic techniques apply discontinuous polarization potential and measure the current response in given time intervals. The alternating current (AC) polarographic techniques are derived from direct current (DC) polarography as described above by imposing a small perturbation voltage of various frequencies upon the main DC polarizing voltage. These methods chiefly detect the adsorption of the participants of the electrode processes.

## Theory

The measurement of electrolytic currents as a function of applied potential imposes certain requirements on the experimental conditions that are determined by properties of the electrode–solution interface. The electrode in the solution of an electrolyte is surrounded by an electrode double layer, with capacity  $C$ , which must be charged when the electrode comes into contact with the solution. The resulting current is termed the charging or capacity current. In order to ensure low variation of the double-layer structure and to obtain sufficient sample conductivity, a suitable strong electrolyte is added. This strong electrolyte is known as an indifferent, supporting, or base electrolyte, which must not interfere with the system to be investigated. As polarographic electrodes, a DME and exceptionally a rotating disk electrode are used. The mean area of the drop in the DME is given by the following expression:

$$\bar{A} = 0.51(mt_1)^{2/3} \quad [1]$$

The instantaneous value at time  $t$  is

$$\bar{A} = 0.85(mt)^{2/3} \quad [2]$$

where  $m$  is the mercury flow rate and  $t_1$  the drop time.

The value  $i_c$  of the charging current depends on the time change of the electrode charge density  $Q$

$$i_c = \frac{dQ}{dt} \quad [3]$$

Consequently, the time change of the electrode surface brings about the charging current that would rapidly decay if the electrode were stationary,

$$i_c = (E - E_z)C \frac{dA}{dt} = 2/3 \times 0.85(E - E_z)Cm^{2/3}t^{-1/3} \quad [4]$$

$E$  is the electrode potential and  $E_z$  is the zero charge potential. This shows that the charging current is infinitely large at the beginning of the drop life and decays with time.

When the electrode potential in the presence of an electroactive substance reaches a value characteristic of the nature of the substance being reduced or oxidized, the current starts to increase exponentially, with the potential thus causing a depletion of the electroactive species (the so-called depolarizer) at the electrode surface. At sufficiently high potentials the current increase slows down and finally levels off forming a constant plateau that is usually called the limiting current ( $i_d$ ) (Figure 2). Under these conditions the concentration of the depolarizer at the electrode is equal to zero and

**Figure 2** Polarograms of (A) 1.0 mol l<sup>-1</sup> HCl, (B) 1.0 mol l<sup>-1</sup> Cd(II) 5 × 10<sup>-4</sup> mol l<sup>-1</sup>.

only the particles reaching the electrode surface by mass transport undergo the electrode reaction.

The current caused by the electron exchange between the solid phase of the electrode and the solution particles results in a change of the overall number of electrons of the depolarizer and is called the Faradaic current

$$i = nF \frac{dN}{dt} \quad [5]$$

Here,  $n$  is the number of electrons exchanged by a single particle,  $F$  equals 96 500 C, and  $dN/dt$  is the number of electroactive particles reaching the electrode surface per unit time.

### Mass-Transfer Contributions

The mass transport toward the electrode has three components: diffusion, migration, and convection.

Migration currents are undesirable in the electrolysis of charged species and are mostly suppressed by adding a 20–100 times surplus of indifferent electrolyte over the concentration of electroactive ions.

The convective component arises, e.g., from the growth of the DME.

Diffusion currents are the electrolytic currents controlled by the diffusion rate of the depolarizer from the bulk solution to the electrode surface and are caused by the concentration gradient due to the depletion of the active substance in the close vicinity of the electrode surface. Consequently, the rate of the electrode reaction must be high enough to obtain currents that are controlled by diffusion only. Therefore, the first and second laws of Fick may be applied, and taking into account the initial and boundary concentration conditions the final Ilkovič equation may be obtained:

$$i_d = 0.732nFcD^{1/2}m^{2/3}t^{1/6} \quad [6]$$

If the Faraday constant is included in the numerical value the instantaneous diffusion current is

$$i_d = 0.706ncD^{1/2}m^{2/3}t^{1/6} \quad [7]$$

By using the mean surface area during the drop life the mean limiting diffusion current can be derived

$$\bar{i}_d = 0.627nFcD^{1/2}m^{2/3}t^{1/6} \quad [8]$$

### Current–Potential Curves for a Reversible Electrode Reaction

Along the rising part of the polarographic wave the Nernst equation is valid:

$$E = E^0 + \frac{RT}{nF} \ln \left( \frac{[\text{Red}_0]}{[\text{Ox}_0]} \right) \quad [9]$$

where  $E^0$  is the standard redox potential,  $n$  is the number of exchanged electrons, and the subscript 0 denotes the concentrations at the electrode surface. Three different cases should be taken into account depending on the species that are present in the bulk of the solution:

1. only the oxidized form is reduced;
2. only the reduced form is oxidized (also in the case of amalgams); and
3. both the oxidized and the reduced forms are present in the solution.

The resulting curves are denoted as cathodic, anodic, and cathodic–anodic curves, respectively. At the potentials where the surface concentration is nonzero the product must diffuse away from the electrode due to the resulting concentration gradient. The net current is expressed by the concentration of the oxidized species

$$i = -\kappa([\text{Ox}] - [\text{Ox}]_0) \quad [10]$$

or of the reduced species

$$i = -\kappa'([\text{Red}] - [\text{Red}]_0) \quad [11]$$

The parameters are denoted as

$$\kappa = 0.627nFD_{\text{ox}}^{1/2}m^{2/3}t^{1/6} \quad [12]$$

$$\kappa' = 0.627nFD_{\text{red}}^{1/2}m^{2/3}t^{1/6} \quad [13]$$

and are often denoted as the Ilkovič constants. Simple arithmetic operations lead to the equation of a reversible polarographic wave:

$$E = E_0 \mp \frac{RT}{nF} \ln \sqrt{\frac{D_{\text{ox}}}{D_{\text{red}}}} \mp \frac{RT}{nF} \ln \left( \frac{\bar{i}}{\bar{i}_d - i} \right) \quad [14]$$

where minus and plus signs denote cathodic and anodic waves, respectively, and  $i_d$  is again the limiting diffusion current. For the cathodic-anodic wave

$$E = E_0 - \frac{RT}{nF} \ln \sqrt{\frac{D_{\text{ox}}}{D_{\text{red}}}} - \frac{RT}{nF} \ln \left( \frac{\bar{i} - \bar{i}_{\text{da}}}{\bar{i}_{\text{dc}} - \bar{i}} \right) \quad [15]$$

where  $i_{\text{da}}$  and  $i_{\text{dc}}$  are anodic and cathodic limiting currents, respectively. The potential at which the current is  $\bar{i} = 1/2 i_d$  is denoted as the half-wave potential  $E_{1/2}$  and, assuming  $D_{\text{ox}} = D_{\text{red}}$  for a reversible system is equal to  $E^0$ :

$$E = E_{1/2} - \frac{RT}{nF} \ln \left( \frac{\bar{i} - \bar{i}_{\text{da}}}{\bar{i}_{\text{dc}} - \bar{i}} \right) \approx E_{1/2} - \frac{RT}{nF} \ln \left( \frac{\bar{i} - \bar{i}_{\text{da}}}{\bar{i}_{\text{dc}} - \bar{i}} \right) \quad [16]$$

The properties of diffusion controlled currents are as follows:

1. Current at a given potential is linearly proportional to the bulk concentration of the redox form undergoing the electrode process.
2. Current is proportional to the square root of the diffusion coefficient, which may be thus evaluated.
3. Mean limiting diffusion current is proportional to the square root of the mercury height  $h^{1/2}$ .
4. The shape of the  $i$ - $E$  curve determines the dependence of  $\ln\{i/(i_d - i)\}$  versus  $E$ , which should be linear with a slope of  $\pm RT/nF$ . (This so-called log-plot analysis is often used for testing the reversibility of a reaction or for estimating the number of electrons ( $n$ ) involved in a given electrode process.)
5. The half-wave potential  $E_{1/2}$  is independent of the concentration and for  $D_{\text{ox}} = D_{\text{red}}$  equals the standard redox potential  $E^0$  of a corresponding redox couple.

#### Finite Charge-Transfer Rate in Electrode Processes (Irreversible or Slow Waves)

If the electron-transfer rate is not high enough it becomes the controlling factor and the observed electrode processes are called irreversible or slow. The Nernst equation is not obeyed in this situation.

Reversibility is not an absolute property in electrochemistry. It depends on the mutual ratio of the electrochemical time constant and the charge-transfer reaction rate. In direct current polarography the method's time constant is given by the drop time, the time available for the establishment of equilibrium, which can be varied only over a limited interval. Electrode reactions with charge-transfer control

are described by the rate constants  $k_{+e}$  and  $k_{-e}$  for reduction and oxidation, respectively. Both constants are potential dependent:

$$k_{-e} = k^0 \exp \left( -\frac{(1-\alpha)nF}{RT} (E - E^0) \right)$$

$$k_{+e} = k^0 \exp \left( -\frac{\alpha nF}{RT} (E - E^0) \right) \quad [18]$$

where  $k^0$  is the standard heterogeneous rate constant corresponding to the rate at  $E^0$  and is expressed in centimeters per second and  $\alpha$  is the transfer coefficient. At potentials far from  $E^0$  the charge-transfer rate becomes so high that the diffusion rate assumes control and a limiting diffusion current is observed.

The half-wave potential is as follows:

$$E_{1/2} = E^0 + \frac{2.3RT}{\alpha nF} \log \left( 0.886 k^0 \sqrt{\frac{t_1}{D}} \right) \quad [19]$$

The following features of irreversible polarographic waves are relevant:

1. The half-wave potential differs from  $E^0$ , depends on  $t_1$ , and the anodic and cathodic waves of the same redox couple have different  $E_{1/2}$  values.
2. The irreversible polarographic wave is more protracted when compared with a reversible wave.
3. The log-plot analysis does not yield the approximate  $n$  value because the slope also includes the  $\alpha$  transfer coefficient.
4. The upper limit of the heterogeneous charge-transfer rate, distinguishable from the diffusion control, is about  $k^0 \ll 0.02 \text{ cm s}^{-1}$ . Larger values of  $k^0$  must be measured by faster techniques (AC or pulse polarography).
5. Irreversible electrode reactions with the participation of complex ions or of organic compounds cannot be analyzed by means of expressions for reversible compounds: more complicated expressions need to be applied.
6. The  $E_{1/2}$  value may also depend on the concentration and on the type of the indifferent electrolyte.

#### Oxygen Behavior

Usually it is necessary to work in the absence of oxygen, since in the potential working zone of the mercury it is active, the following reduction reactions taking place:

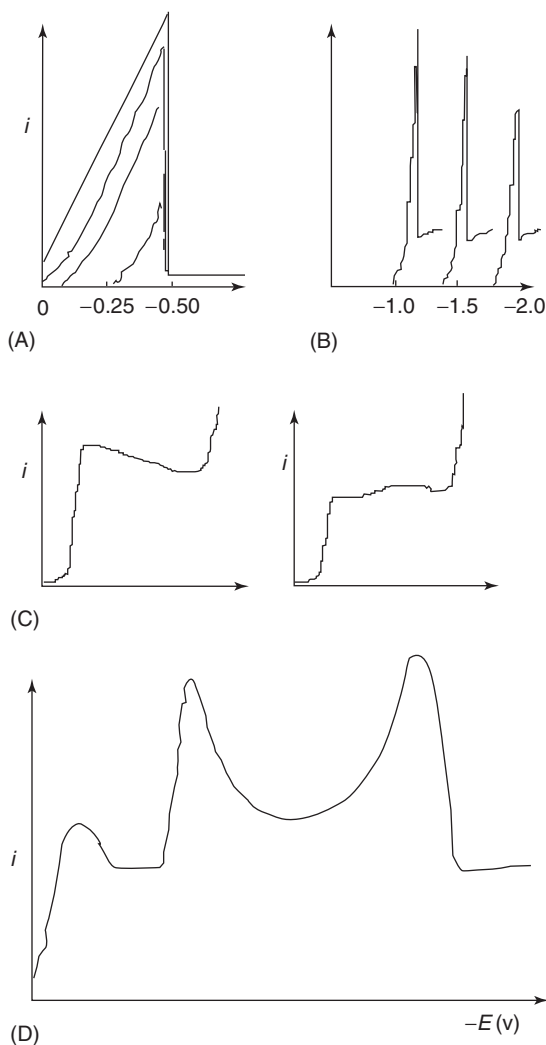

which give two reduction waves for potentials  $\sim -0.1$  and  $-0.9 \text{ V}$  (versus SCE), which may interfere

with the polarographic waves of the analytes to be determined. The nonremoved oxygen traces (a nitrogen flow of sulfite is used) defines, together with the residual current, the detection limit of the technique. These reduction waves of oxygen are, on the other hand, the basis of the electrochemical Clark probe for dissolved oxygen in waters.

### Polarographic Maxima

Certain anomalies related to polarographic curves are known by this name and consist in sharp intensity increases on the rising zone of the curve or on that in which the diffusion limit is attained. Depending on both their morphology and origin they are classified as first, second, and third type maxima. Besides, those corresponding to the first kind can be positive and negative (Figure 3).

**Figure 3** Polarographic maxima: A, positive first kind maxima; B, negative first kind maxima; C, second kind maxima; D, third kind maxima.

The high increase of intensity regarding the different types of maxima is always due to the internal movements of the mercury drop, which in turn induces movements in the adjacent zone of the solution. Consequently, the flow rate of the electroactive species toward the electrode is higher than that which would take place by diffusion.

Polarographic maxima may be eliminated by addition to the solution of tensioactive substances. At present, Triton X-100 is the most widely used compound owing to the higher stability of its solutions with time, together with the fact that since it is a nonionic tensioactive agent, it is, thus, absorbed within a wide range of potentials and is unlikely to chemically interact with other compounds of the solution.

The use of the static mercury electrode enhances the elimination of polarographic maxima, since measurements are carried out with the mercury not flowing.

### Quantification

Regardless of the degree of reversibility of the electrode process, both reversible and irreversible processes can be used for qualitative identification (using  $E_{1/2}$ ), and the quantitative determination based on the Ilkovič equation. If the classical DC polarographic method is applied the lower limit of determination is in the region of  $2 \times 10^{-5} \text{ mol l}^{-1}$ . This sensitivity is not sufficient in comparison with the more advanced analytical methods. The evaluation is carried out by calibration curves or by standard addition.

### Instrumentation

The experimental arrangement in DC polarography is one of the simplest in chemical instrumentation: in essence it consists of the polarizable working (measuring) electrode, the unpolarizable reference electrode, the voltage source, the current measuring device, and the electrolytic vessel. The indicator electrode, i.e., a DME in polarography, is polarized by the voltage source of a low-output resistance (e.g., a ramp generator), which polarizes the electrode with continuously increasing voltage. An unpolarizable electrode with a defined potential (like standard calomel electrode) is used as a reference electrode. This electrode system is immersed into an electrolytic vessel containing the solution to be examined. The current flowing through the electrode system is measured by the current-measuring device and depends on the voltage applied to the working (measuring) electrode.

In recent polarographs, potentiostatic systems with three electrodes are employed (an auxiliary platinum electrode in addition to both the dropping mercury

and the reference electrodes) since they allow to compensate the ohmic drop of the solutions when working in nonexclusively aqueous media. With the former system, thus, the distortion of the polarographic wave is avoided.

The recent introduction of digital systems controlled by microprocessor allow the replacement of the systems of mechanical voltage scanning by digital/analog converters, which offer a higher reproducibility. Voltage variations as a function of time are not completely linear any longer, showing a stepping appearance instead, the voltage remaining fixed in DC polarography during the drop life. The knocker's blow implies not only the beginning of the reading synchronism, but it is also used to increase the voltage to be applied in the next drop.

### Mercury Electrode

The DME consists of mercury droplets flowing out under constant pressure from a mercury reservoir-connected capillary (inner diameter 0.05–0.07 mm;

length 10–15 cm). The natural drop time is within the range 3–10 s. The DME is characterized by its drop time  $t_1$  and by the flow rate of mercury  $m$ , which is in the range  $1\text{--}4\text{ mg s}^{-1}$ . Drop-time measurements must take place under reproducible conditions, e.g., the mercury column height, the supporting electrolyte, the same electrode potential. The drop time may be externally controlled by a device (knocker) that periodically dislodges the mercury drop from the tip of the capillary as in sampled (tast) polarography and in advanced methods. Since  $t_1$  and  $m$  depend on column height,  $mt_1$  and the drop size  $A$  are constant and independent of the column height. The size of the drop changes only with changes in the surface tension of mercury. When the surface tension is changed, e.g., by changing the potential, the solution, the surfactant, etc., the drop time changes but the flow rate remains constant. In newly developed capillary types the tip of the capillary has a spindle-shaped inner space; these spindle-shaped capillaries have a highly reproducible drop. An improvement over the classical DME is the static mercury drop

**Figure 4** Modern polarograph, constituted by a potentiostatic system with three electrodes (static mercury, AgCl/Ag reference, and Pt auxiliary), knocker for synchronism and needle valve allowing to control the size of the hanging drop. With permission of AMEL.

electrode in which a needle or other kind of valve controls the mercury flow through the capillary and the drop growth (Figure 4). The current measurement is carried out when the drop area does not change with time. This kind of electrode is used as a hanging mercury drop electrode applied in stripping analysis or as a periodically renewed hanging electrode that may replace the DME. The surface after the drop formation remains constant. The DM is sensitive to mishandling. The capillary should not be left in the solution to be examined when the mercury is not flowing.

The advantages of the static electrode over the dynamic electrode are several. On the one hand, the current measurement is carried out without varying the electrode surface at all, which enhances the decrease of the capacitive current. On the other hand, since the mercury flow is nonexistent the undesirable polarographic maxima tend to disappear; thus, achieving more neat polarograms for the solution, since the solution that is in contact with the electrode remains still. Finally, it is possible to easily obtain voltammograms instead of polarograms, since the whole scanning can be performed with only one mercury drop hanging from the capillary. The drop is renewed in this latter case several times just before the voltage scanning takes place; thus, the advantage of the easiness of reproducibility regarding the mercury electrode remains against solid electrodes, which are more likely to present the memory phenomenon.

### Reference Electrode

The potential of the working electrode is referred to nonpolarizable reference electrode, the potential of

which does not depend on the current flowing through the solution. The current is usually very low so that the last term in the following equation can be neglected:

$$E_{\text{appl}} = E_{\text{WE}} - E_{\text{RE}} + iR \quad [20]$$

### Introduction

Ever since the development of direct current (DC) polarography, much efforts have been undertaken to compensate for the following three main limitations:

1. The drawback of DC polarography with regards to sensitivity is the current required to change the potential of the dropping mercury

electrode (DME) to the required value: at a depolarizer concentration of  $10^{-5} \text{ mol l}^{-1}$ , this time-averaged charging current is comparable to the Faradaic current.

2. Lack of resolution of the sigmoid-shaped waves (e.g., DC polarography, normal pulse polarography (NPP)). In order to sufficiently distinguish two polarographic waves so as to be able to measure their corresponding half-wave potentials and limiting current values, it is necessary that the former half-wave potentials should differ in more than 200 mV. All subsequent polarographic techniques, in which the obtained response is in the form of a peak (derivative polarography, square-wave polarography (SWP), alternating current (AC) polarography, differential

**Figure 1** Several polarographic techniques obtained using a digital polarograph. The DC technique has been obtained with a dynamic mercury electrode, whereas those of DC fast and AC have been attained with a static electrode and current integration. mt = measuring time, dl = drop life,  $t$  = time,  $A$  = electrode surface,  $V$  = voltage applied to the working electrode. The scanning are cathodic, i.e., toward more negative voltages, giving rise to cathodic currents.

pulse polarography (DPP), etc.) present a higher resolution, a difference of only  $\sim 50$  mV being sufficient to be able to discriminate two substances presenting close half-wave potentials.

3. As observed in **Figure 1** (DC polarography), the noise of the oscillations increases considerably after the reduction of a substance. Thus, making the calculation of the limiting current of any other compound, which is being reduced after the first substance, is difficult, especially when this compound is present at low concentrations. This difficulty decreases when peak-shaped polarograms are attained, for which the signal returns to the baseline.

## Evolution of Polarographic Techniques

In order to solve the above-mentioned drawbacks different solutions have been proposed, although nowadays several can be considered obsolete. In

**Table 1** Polarographic techniques

Technique	Resolution	Limit of determination (for lead) ( $\text{mol l}^{-1}$ )
<i>Polarograms with sigmoid shape</i>		
DC	200 mV	$10^{-4}$
Rapid	200 mV	$10^{-4}$
DC fast	200 mV	$10^{-5}$
Differential	50 mV	$10^{-5}$
NPP	200 mV	$10^{-6}$ – $10^{-7}$
<i>Polarograms with peak shape</i>		
Derivative	50 mV	$10^{-5}$
AC	50 mV	$10^{-6}$ – $10^{-7}$
SWP	50 mV	$10^{-7}$ – $10^{-8}$
DPP	50 mV	$10^{-7}$ – $10^{-8}$

DC, direct current; NPP, normal pulse polarography; AC, alternating current; SWP, square wave polarography; DPP, differential pulse polarography.

**Table 1**, an account of the most significant contributions is presented.

One of the first interesting contributions was directed toward the elimination of the noise produced

**Figure 2** Variation of the drop surface, and the intensities of the capacitive ( $i_c$ ) and diffusion ( $i_d$ ) currents with time.

by the capacitive current, which contributes, especially in the beginning, to the growth of the mercury drop. This is due to the fact that for a constant mass flow rate of mercury, the variation rate of the drop's surface is very fast, which is comparable to a condenser whose plates are changing their surface very rapidly and, therefore, the charging current will be initially very high (see **Figure 2**).

The equations giving the intensity variations of both the diffusion and capacitive currents, together with their corresponding ratio, are

$$i_c = km^{2/3}t^{-1/3} \quad [1]$$

$$i_d = k'm^{2/3}t^{1/6} \quad [2]$$

$$i_d/i_c = k''t^{1/2} \quad [3]$$

which reveal that the signal-to-noise ratio improves with time. Thus, in rapid polarography the first 20 ms of the drop's life are neglected in order to subsequently integrate the current during the rest of the drop's life. This option implied the introduction of a synchronization element, the knocker, nowadays present in all modern polarographs: a blow of the knocker releases the previous drop and defines the starting time of the new drop (from which the first 20 ms are discarded before measuring the current). The period of time between two successive blows of the knocker will define the drop's life. Fast polarography can be considered as an evolution of rapid polarography, in which the current measurement is carried out only at the end of the drop's life and where the drop's surface remains almost practically constant with time.

## Alternating Current Polarography

This method is based on superimposition of a small amplitude sine-wave voltage  $E_{\sim}$  over the linear voltage ramp (see **Figure 1**).

The  $E_{\sim}$  frequency ranges from 10 Hz to  $\sim 10$  kHz. The resulting current contains, in addition to the filtered-off DC component, the AC component  $i$ , which is proportional to the total cell admittance

$$Y = Y' + jY'' \quad [4]$$

where  $Y'$  and  $Y''$  are the real and the imaginary admittance components, respectively.

After amplification and rectification, the total AC magnitude was originally recorded as a function of DC voltage. The cell impedance in the simplest case is composed of an ohmic solution resistance  $R_s$  in series with the parallel combination of the electrode double-layer capacity  $C$  and the Faradaic impedance component  $Z_F$ ; the alternating current is a vector with a definite phase in relation to the applied AC perturbation voltage. Measurement of only total alternating current offers no particular advantage during a detailed electrochemical investigation. AC polarography became increasingly attractive after the introduction of more sophisticated instrumentation based on phase-sensitive detection with automatic solution resistance compensation. This procedure consists of measuring the two curves: one current component, also known as the real or the resistive component, which is in phase with  $E_{\sim}$ , and the other, the imaginary or the quadrature component, which is phase-shifted  $90^\circ$  with respect to the  $E_{\sim}$  vector. If the amplitude of  $E_{\sim}$  is precisely known, cell admittance  $Y(\omega)^0$  or impedance  $Z(\omega)$  at a given frequency  $\omega$  may be calculated as

$$i_{\sim} = \frac{E_{\sim}}{Z(\omega)} = Y(\omega)E_{\sim} \quad [5]$$

This information may be analogously obtained by finding the absolute value of the AC vector and the phase shift of  $i_{\sim}$  in reference to  $E$ . Appropriate  $R_s$  compensation is crucial in phase-sensitive AC polarography because the  $IR$  drop causes a phase error that is eliminated only after laborious vector analysis. The in-phase component of a phase-sensitive AC polarogram of a blank solution without any electroactive compounds should be a zero line since

$$Y'\omega = \frac{1}{R_s} \rightarrow 0 \quad [6]$$

and the double-layer capacitance for the imaginary component

$$Y''(\omega) = \omega C(E) \quad [7]$$

The double-layer structure and adsorption of various surface-active substances may be examined by this method, which replaces cumbersome balancing bridge measurements.

The Faradaic peak-shaped contributions in both real and imaginary AC curves, denoted as  $Y'_F$  and  $Y''_F$ , respectively, are found in the potential region of the polarographic wave. A general case with a finite charge-transfer rate relates these Faradaic components

to the kinetic parameters by

$$Y_F' = nFA \frac{\xi + 1}{2\xi^2 + 2\xi + 1} \left[ c_{\text{Red}}' \frac{\delta k_{+e}}{\delta E} - c_{\text{Ox}}' \frac{\delta k_{-e}}{\delta E} \right] \quad [8]$$

$$Y_F'' = nFA \frac{\xi}{2\xi^2 + 2\xi + 1} \left[ c_{\text{Red}}'' \frac{\delta k_{+e}}{\delta E} - c_{\text{Ox}}'' \frac{\delta k_{-e}}{\delta E} \right] \quad [9]$$

where  $c'$  is surface concentration and

$$\xi = \frac{k_{+e}}{\sqrt{2\omega D_{\text{Ox}}}} + \frac{k_{-e}}{\sqrt{2\omega D_{\text{Red}}}} \quad [10]$$

Both Faradaic components are proportional to bulk concentration and  $Y_F''$  is a signal completely without charging components, with a zero line ideally suited to analytical applications. Furthermore, phase-sensitive AC polarography gives instantaneous information about reversibility at a given  $\omega$  by comparing the ratio of  $Y_F'$  and  $Y_F''$ .

A reversible electrode reaction corresponds to the limit  $\xi \rightarrow 0$ , hence  $Y_F' = Y_F''$ . In contrast, the totally irreversible process is characterized by  $\xi \rightarrow 0$  and  $Y_F'' \rightarrow 0$ . This AC technique also determines the double-layer capacity in the presence of a quasireversible electrode reaction by utilizing sufficiently high frequency, since  $\omega \rightarrow \infty$ , and hence  $Y' \rightarrow 0$  and  $Y'' \rightarrow \omega c$ .

The kinetic parameters  $k^0$  and  $\alpha$  are evaluated by plotting  $\xi$  versus  $E$ :

$$\xi = \frac{Y_F''}{Y_F' - Y_F''} = \frac{k_{+e}}{\sqrt{2\omega D_{\text{Ox}}}} = \frac{k_{-e}}{\sqrt{2\omega D_{\text{Red}}}} \quad [11]$$

yielding two linear asymptotes at far positive and negative potentials with respect to  $E_{1/2}$ .

The transfer coefficient is calculated from the slope and  $k^0$  and  $E^0$  from the coordinates of the asymptotes' intercept. The appropriate method for the determination is based on the Faradaic phase angle

$$\tan \varphi = \frac{Y_F''}{Y_F'} \quad [12]$$

which is plotted versus  $\sqrt{\omega}$  for the  $k^0$  determination. The potential of the maximum on a cotan versus  $E$  plot yields the  $\alpha$  value. Admittance or impedance data displayed as complex plane plots are often used.

Electroactive species adsorption is sensitively indicated by this method, which thus determines whether redox system properties are obscured by a specific type of interaction with the electrode. Strongly absorbable electroinactive compounds yield peaks on the AC curves located at potentials of the adsorption-desorption process. However, they are much narrower and their frequency dependence differs markedly from the Faradaic peaks. Such peaks were also used for determination of surface-active

compounds. In general, AC polarography is not very sensitive, in particular in irreversible processes without adsorption.

## Pulse Polarography

In pulse methods, the procedures are based on the application of pulse changes of potential and the current response is measured at a suitable time relative to the time of the pulse. The concept includes three methods: NPP, DPP, and SWP.

Pulse techniques improve detection limits since they benefit from the different variation of diffusion and capacitive current intensities with time: when carrying out measurements at the pulse end, the capacitive current is practicably negligible, the value of the Faradaic current still being significant (see eqn [3] and Figure 3).

NPP keeps the DME at a constant potential before the start of the Faradaic current; then, almost at the end of the drop's life, a voltage pulse is applied, whose amplitude gradually increases from drop to drop. The duration of the pulse is  $\sim 200$  ms. The current is usually measured shortly and before the pulse end ( $\sim 20$  ms after the pulse edge) and is recorded versus the pulse amplitude. The current-potential relationship for a reversible process is

$$i = nFcA \sqrt{\frac{D}{\pi\tau} \left( \frac{1}{1+P} \right)} \quad [13]$$

where  $P = \exp(nF/RT)(E - E_{1/2})$  and  $\tau$  is the pulse duration. As the pulse voltage becomes more negative than  $E_{1/2}$ , the value of  $P$  approaches zero, yielding a limiting current given by the Cottrell equation:

$$i = nFcA \sqrt{\frac{D}{\pi\tau}} \quad [14]$$

This mode is about seven times more sensitive than classical DC polarography.

**Figure 3** (A) Sudden variation of the potential, (B) behavior of the diffusion ( $i_d$ ), and capacitive ( $i_c$ ) currents with time.  $t_a$  and  $t_b$  are the times used in the measurement of the current.

The shape of the curve is that of a normal DC polarogram. In irreversible processes, NPP may also determine the kinetic parameter  $k^0$ . Only the upper limit for  $k^0$  is higher than in DC polarography since the time is now of the order of milliseconds in contrast with the drop time  $t_1$  in DC polarography.

DPP (Figure 4) differs from NPP when prior to the pulse application the potential is not constant but is replaced by a ramp voltage with DC polarographic characteristics. The pulse amplitude is constant and the measured current is displayed as the difference between the current sampled closely before pulse application and the current sampled at the pulse end.

If the polarographic  $i$ - $E$  equation is now differentiated as

$$i = i_d \frac{1}{1 + P} \quad [15]$$

and the Cottrell equation is substituted for  $i_d$ , the relationship for the DPP with a reversible process is

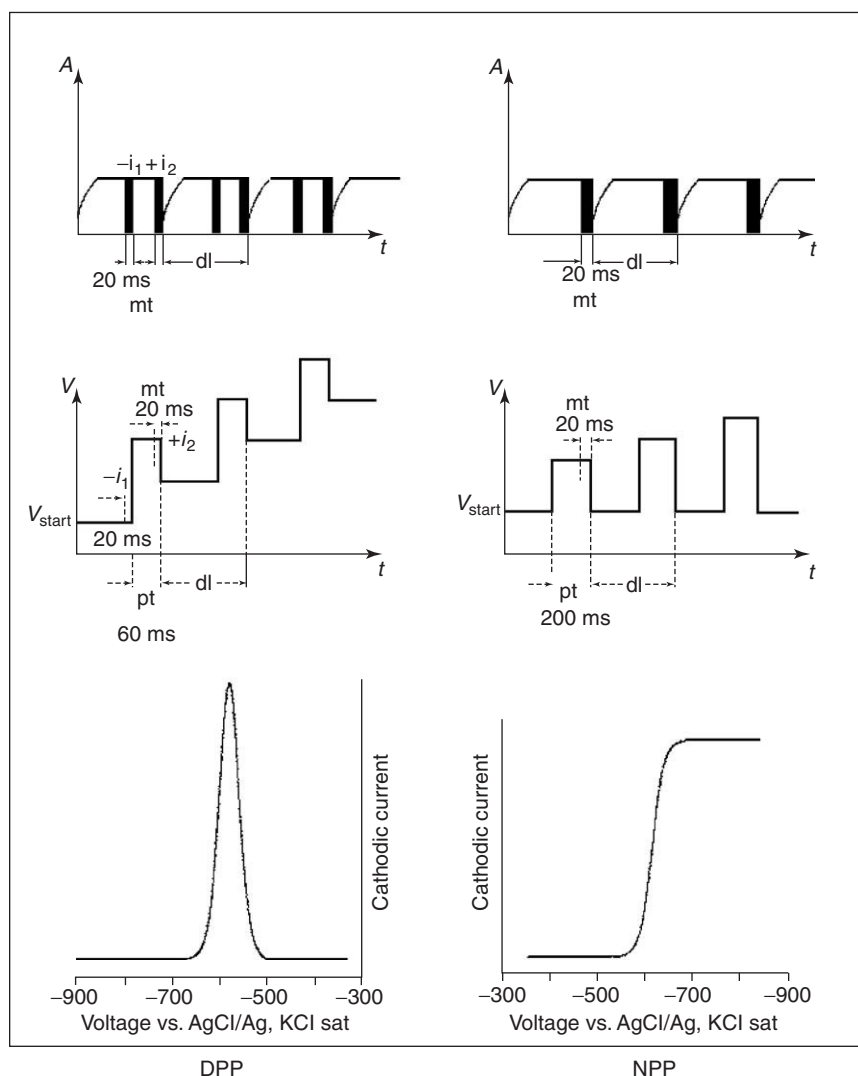

$$i = \frac{n^2 F^2}{RT} A c \Delta E \sqrt{\frac{D}{\pi \tau}} \cdot \frac{P}{(1 + P)^2} \quad [16]$$

This equation is only valid for small values of pulse amplitude  $E < RT/nF$ . The  $i$ - $E$  curve is a derivative of the classical DC polarographic wave. The peak current is

$$i = \frac{n^2 F^2}{4RT} A c \Delta E \sqrt{\frac{D}{\pi \tau}} \quad [17]$$

The peak potential is related to  $E_{1/2}$  by

$$E_p = E_{1/2} - \frac{\Delta E}{2} \quad [18]$$

**Figure 4** DPP and NPP polarographies. Variation of the mercury drop area and voltage with time using the static mercury electrode. dl = drop life, mt = measuring time; pt = pulse time; A = electrode area,  $t$  = time;  $V$  = working electrode voltage.

The solution for  $i$ - $E$  curves is also available for a slow electrode reaction or for considering electrode sphericity.

In SWP, the polarization potential is a linear varying voltage ramp over which a small amplitude square-wave signal, usually 225 Hz and 1–50 mV amplitude, is superimposed. This differs from NPP and DPP in that perturbation continues during the whole life of the drop and the response readout is positioned at a time of negligible time change of the electrode surface. The signal, measured as a function of the linear varying potential, is the difference of current samples obtained at the end of each half-cycle of the square-wave signal; the DC signal component is filtered off. The resulting  $i$ - $E$  curve is a peak described for a reversible reaction by the equation

$$i = \frac{n^2 F^2}{RT} c \Delta E \sqrt{\frac{D}{\pi \tau}} \cdot \frac{P}{(1+P)^2} L \quad [19]$$

In this equation,  $L$  is the constant of the instrument defined as

$$L = \sum_{m=0}^{\infty} \frac{(-1)^m}{(m + t/\tau)^{1/2}} \quad [20]$$

$\Delta E$  is the square wave amplitude,  $t$  is the time measured from the beginning of the half-cycle and is the half-period of the square wave. The peak half-width,  $W_{1/2}$ , for small  $\Delta E$  is given by

$$W_{1/2} = 3.52 \frac{RT}{nF} = \frac{90.5}{n} \text{ mV at } 25^\circ\text{C} \quad [21]$$

The theory of slow charge-transfer reactions reveals that the peak height strongly decreases in the range of rate constants  $k^0 = 10^{-1}$ – $10^{-4} \text{ cm s}^{-1}$ ; below this value it is almost completely insensitive toward the  $k^0$  change and yields peaks  $\sim 20$  times smaller than those in the reversible case.

## Introduction

Polarography is a voltammetric technique in which chemical species (ions or molecules) undergo oxidation (lose electrons) or reduction (gain electrons) at the surface of a dropping mercury electrode (DME) at an applied potential. Polarography only applies to the DME. The resultant reduction or oxidation current is recorded against the applied potential to yield the analytical parameter. Polarography may be used simply as an analytical tool or as a diagnostic method to interpret mechanisms and rates of electrode

chemical reactions. Electrode surface redox reactions may occur with both inorganic and organic chemical species, although this article will deal solely with the inorganic applications of polarography.

Polarography was first introduced in 1922 by Heyrovsky; however, by the mid-1950s its usefulness as an analytical technique was superseded by spectroscopic techniques such as atomic absorption spectroscopy (AAS). For example their popularity for dissolved trace metal analysis was due to their greater sensitivities (ca.  $<0.1 \text{ mmol l}^{-1}$  compared to typically  $>0.1 \text{ mmol l}^{-1}$  for polarography), elemental diversity, flexibility, and ease of use. However, during the 1970s and 1980s polarographic techniques were more widely adopted owing to advances in instrumental design, particularly in enhancement in

The solution for  $i$ - $E$  curves is also available for a slow electrode reaction or for considering electrode sphericity.

In SWP, the polarization potential is a linear varying voltage ramp over which a small amplitude square-wave signal, usually 225 Hz and 1–50 mV amplitude, is superimposed. This differs from NPP and DPP in that perturbation continues during the whole life of the drop and the response readout is positioned at a time of negligible time change of the electrode surface. The signal, measured as a function of the linear varying potential, is the difference of current samples obtained at the end of each half-cycle of the square-wave signal; the DC signal component is filtered off. The resulting  $i$ - $E$  curve is a peak described for a reversible reaction by the equation

$$i = \frac{n^2 F^2}{RT} c \Delta E \sqrt{\frac{D}{\pi \tau}} \cdot \frac{P}{(1+P)^2} L \quad [19]$$

In this equation,  $L$  is the constant of the instrument defined as

$$L = \sum_{m=0}^{\infty} \frac{(-1)^m}{(m + t/\tau)^{1/2}} \quad [20]$$

$\Delta E$  is the square wave amplitude,  $t$  is the time measured from the beginning of the half-cycle and is the half-period of the square wave. The peak half-width,  $W_{1/2}$ , for small  $\Delta E$  is given by

$$W_{1/2} = 3.52 \frac{RT}{nF} = \frac{90.5}{n} \text{ mV at } 25^\circ\text{C} \quad [21]$$

The theory of slow charge-transfer reactions reveals that the peak height strongly decreases in the range of rate constants  $k^0 = 10^{-1}$ – $10^{-4} \text{ cm s}^{-1}$ ; below this value it is almost completely insensitive toward the  $k^0$  change and yields peaks  $\sim 20$  times smaller than those in the reversible case.

## Introduction

Polarography is a voltammetric technique in which chemical species (ions or molecules) undergo oxidation (lose electrons) or reduction (gain electrons) at the surface of a dropping mercury electrode (DME) at an applied potential. Polarography only applies to the DME. The resultant reduction or oxidation current is recorded against the applied potential to yield the analytical parameter. Polarography may be used simply as an analytical tool or as a diagnostic method to interpret mechanisms and rates of electrode

chemical reactions. Electrode surface redox reactions may occur with both inorganic and organic chemical species, although this article will deal solely with the inorganic applications of polarography.

Polarography was first introduced in 1922 by Heyrovsky; however, by the mid-1950s its usefulness as an analytical technique was superseded by spectroscopic techniques such as atomic absorption spectroscopy (AAS). For example their popularity for dissolved trace metal analysis was due to their greater sensitivities (ca.  $<0.1 \text{ mmol l}^{-1}$  compared to typically  $>0.1 \text{ mmol l}^{-1}$  for polarography), elemental diversity, flexibility, and ease of use. However, during the 1970s and 1980s polarographic techniques were more widely adopted owing to advances in instrumental design, particularly in enhancement in

solid-state electronic circuitry, which led to enhanced sensitivities. In addition, the applications of polarography widened, along with the technique's relatively low capital and running costs. More recently advances in the technique may be attributed to the design of the DME and interfacing with information technology (enabling quicker analyses; the electrode has minimum interference, consuming very little mercury and is sealed and simple to handle, as well as economical to use).

Polarographic analysis has been applied to a wide variety of samples including natural waters, biological, mineral, and environmental samples. A summary of the applications is shown in **Table 1**. In addition, **Table 1** illustrates the typical detection limits encountered for each element, although this will vary depending upon the sample solution conditions. All the applications quoted in **Table 1** are for differential pulse polarography (DPP; discussed later). Lower detection limits may be achieved using techniques

such as stripping voltammetry. Stripping voltammetry, both anodic and cathodic, has advanced over the last decade enabling the detection of trace levels of organic and inorganic chemical species in aqueous solutions (typical limits of detection  $<10^{-9} \text{ mol l}^{-1}$ ), surpassing the detection limits of polarography for certain analyte determinations, and indeed advanced spectroscopic techniques.

Essentially, direct current (DC) polarography yields detection limits in the orders of  $10^{-5}$ – $10^{-6} \text{ mol l}^{-1}$ . However, if the applied potential scan is either in the DPP or the alternating current (AC) mode then the detection limits may be enhanced to  $10^{-7}$ – $10^{-8} \text{ mol l}^{-1}$ , widening their analytical applications.

The major advantages using polarography for inorganic analysis may be summarized: (1) comparatively inexpensive equipment is required, (2) ability of the technique to distinguish between elemental oxidation states (i.e., Cr, As), (3) ability of the technique to establish the chemical form of elements

**Table 1** Summary of DP polarographic inorganic applications

<i>Element</i>	<i>Application</i>	<i>DL (<math>\mu\text{mol l}^{-1}</math>)</i>	<i>Comments<sup>a</sup></i>

(e.g., characterization and quantification of metal-organic complexation in natural waters), (4) simultaneous elemental analysis (e.g., Cu, Pb, Cd, Zn), and (5) sensitivity (down to  $10^{-8} \text{ mol l}^{-1}$ ).

As with all analytical techniques polarography has a number of limitations; these are (1) technique is not sensitive enough for direct ultratrace elemental analysis (in these circumstances the use of stripping voltammetry may be considered), (2) long analysis times (minutes compared to seconds for other analytical techniques such as AAS, ICP-AES) are required, (3) operator experience more critical (understanding of electrode processes is essential), in data interpretation, (4) limited elemental range owing to the constraints of the voltage window of the DME, and (5) toxic nature of mercury has recently limited its use.

However, the present discussion is to highlight the extensive capabilities of polarography for inorganic analysis. The discussion is by no means complete in both analytes detectable and sample application. However, it does serve to indicate the range of elements, which may be determined, along with the approximate detection limits for each application.

## Basic Concepts

Polarography is just one of many electrochemical techniques available to the analytical chemist. Polarography is restricted to applications using the DME. This is termed the working electrode. The DME guaranteed its popularity amongst electrochemists because (1) the electrode surface is continuously renewed and (2) it has a large hydrogen overpotential leading to a wide electrode potential window.

During the determination a changing negative voltage (cathodic) is applied at the electrode, reducing the analyte of interest (or conversely oxidizing the analyte if an anodic potential scan is applied at the electrode surface):

Under such conditions transfer of the analyte from the bulk solution to the electrode surface is principally by diffusion. A typical DC polarogram is presented in **Figure 1**. The half wave potential ( $E_{1/2}$ ) is characteristic of the analyte and hence yields qualitative analytical data. The analyte reduction current, produced at the electrode surface, is the limiting diffusion current ( $i_d$ ) which is proportional to the concentration of the analyte in the solution, hence providing the quantitative information. Calibration is performed by internal standard additions or the construction of a calibration curve.

Ilkovic defined the theoretical relationship between the analyte concentration in the bulk solution

**Figure 1** Typical polarogram of the reduction of an electro-active species.

to the diffusion current such that,

$$i_d = 607nD_{\text{ox}}^{1/2}m^{2/3}t^{1/6}c_{\text{ox}}$$

where  $i_d$  is the diffusion-controlled current (A),  $n$  the number of Faradays of electricity per molar unit of electrode reaction,  $D_{\text{ox}}$  the diffusion coefficient of analyte ( $\text{cm}^2 \text{ s}^{-1}$ ),  $m$  the flow rate of mercury through DME ( $\text{mg s}^{-1}$ ),  $t$  the drop time (s), and  $c_{\text{ox}}$  the concentration of analyte ( $\text{mol l}^{-1}$ ).

Knowledge of whether an electrode process is reversible or irreversible is crucial in interpreting polarograms. The reversibility of the electrode reaction depends upon the rate of reaction of the following stages in an electrode process (1) the charge transfer step, (2) the chemical reaction, (3) diffusion of analyte to the electrode, and (4) adsorption processes.

For a more extensive treatment of electrode reversibility and the theory of polarography the reader can refer to the Further Reading section.

## Instrumentation

Polarographic analysis requires a three-electrode circuit containing the working electrode (DME), counter-electrode (usually a platinum wire or graphite rod) and finally the reference electrode, generally being either a standard calomel electrode (SCE) or a silver/silver chloride reference electrode.

The three-electrode system is connected to the polarographic analyzer which maintains the working electrode potential using a potentiostat which also controls the potential scan applied at the DME whilst monitoring reduction/oxidizing currents.

## Limitations of Polarography

A chemical species will be responsive at the DME provided that it undergoes oxidation or reduction at a potential that lies within the voltage window of a

**Figure 2** Typical reduction potentials (vs. SCE) of a number of metallic species within the potential window of a DME (acetate buffer, pH=5).

DME (an analyte which is not responsive within these limits may be derivatized to a chemical species which is, discussed later). The limits of the voltage window are set by (1) the oxidation of mercury ( $>0.1$  V – SCE) and (2) the reduction of the hydronium ion ( $-0.8$  to  $-2.0$  V depending on the solution pH, increasing the pH will shift the reduction potential cathodically).

**Figure 2** illustrates just some of the analytes whose redox potential lie within the voltage window of a DME.

In addition dissolved oxygen is electroactive and will give rise to two reduction waves, potentially masking the analyte of interest, therefore oxygen must be stripped from solution before analysis can proceed, usually by purging the sample with argon or pure nitrogen.

Inorganic applications are generally carried out in aqueous solution, which may require the addition of a supporting electrolyte (e.g.,  $0.1 \text{ mol l}^{-1}$  KCl) to lower the solution resistance. However, care must be taken to use the highest purity of reagent available to minimize sample contamination.

Careful choice of supporting electrolyte has to be made owing to possible complexation of the analyte with the components of the supporting electrolyte, which may lead to a shift in the reduction potential. If there is a lowering of the free energy, resulting from complexation, then the  $E_{1/2}$  will shift to more negative potentials. This may be advantageous, as interference from overlapping analyte reduction peaks may thus be eliminated or reduced (see the section ‘Applications’; Ni and Co). Complex formation constants can also be evaluated from this shift in the  $E_{1/2}$ .

The solution pH may significantly alter the speciation and hence the electroactive behavior of analytes involved in acid/base reactions. For example, a protonated form may be electroactive whereas another form of the same analyte may not, or may appear at a different reduction potential. Therefore, analyte solutions need to be buffered at an optimum pH during analysis, to maintain a constant analyte current response.

**Table 2** Examples of electrolytes used in inorganic polarographic analysis

$0.1 \text{ mol l}^{-1}$ KCl
$0.1 \text{ mol l}^{-1}$ $\text{KNO}_3$
$0.1 \text{ mol l}^{-1}$ $\text{NH}_3/\text{NH}_4\text{Cl}$
$0.1 \text{ mol l}^{-1}$ KCNS
$0.1 \text{ mol l}^{-1}$ EDTA (pH = 7)
$1 \text{ mol l}^{-1}$ HCl
$1 \text{ mol l}^{-1}$ NaOH/KOH
$0.2 \text{ mol l}^{-1}$ tartrate/ $\text{NH}_3$ (pH = 9)
$0.1 \text{ mol l}^{-1}$ citrate/ $\text{NH}_3$ (pH = 3)
$0.25 \text{ mol l}^{-1}$ oxalic acid + $(\text{NH}_4)_2$ -oxalate (pH = 4)

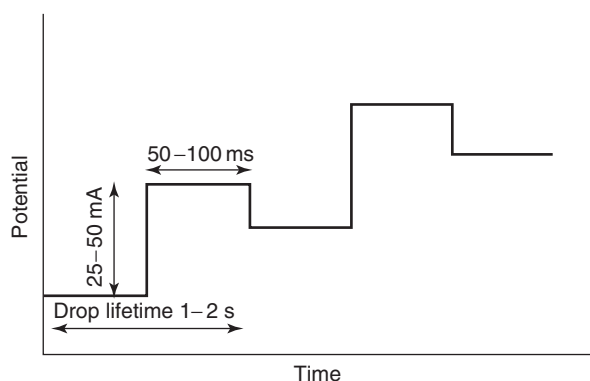

**Table 2** illustrates some of the reported supporting electrolytes used in inorganic polarographic analysis.

## Mode of Potential Scans

During DC polarographic analysis a linearly changing potential with time is applied at the working electrode. Historically DC was the first mode of potential scan, but its downfall was its limited sensitivity (detection limits;  $\sim 10^{-5} \text{ mol l}^{-1}$ ). At such concentrations the charging or capacitance current ( $i_c$ ) is similar to the faradaic current ( $i_f$ ) of the current resulting from the electrode surface redox reaction. Even sampling the current at the end of the drop lifetime only increases the sensitivity slightly due to the depletion of analyte at the surface of the drop.

This limitation led to the development of normal pulse polarography (NPP) introduced by G.C. Barker, which minimized background responses (principally the capacitance current of the growing mercury drop) and maximized the analytical response. NPP requires the application of a series of potential pulses at the working electrode for each drop. The pulse increases in potential with every drop. The current is sampled just before the end of the drops lifetime, minimizing the effect of the capacitance current on the faradaic current. As the potential pulse for each drop starts at a potential lower than the redox potential, no depletion of the analyte would have occurred.

The limit of detection may be lowered further by one or two orders of magnitude using this potential scan mode. Improvement on NPP has occurred with the development of DPP. The difference between NPP and DPP is that the pulse does not return to a constant potential, instead the applied pulses (amplitude being typically 25–50 mV) are superimposed on a linear voltage profile (**Figure 3**), for between 50 and 100 ms. The pulse is applied toward the end of the drop's lifetime with the analyte redox current being measured at the DME before and after the pulse. This differential current is then plotted against the average potential to obtain the differential pulse

**Figure 3** Diagram to illustrate the characteristics of a differential pulse potential scan.

polarogram. Generally, a peak-shaped output is obtained (where  $E_p$  is similar to  $E_{1/2}$ ) during the analytical stage. The peak current is proportional to the electroactive analyte in solution. Limits of detection with DPP are of the order  $10^{-8}$ – $10^{-9}$ .

Another form of applied potential scan involves the superimposition of an AC voltage on the applied potential ramp, which has been shown to enhance sensitivity over DPP. For a more comprehensive description of pulse and AC techniques describing subtle variations, the reader can refer to the Further reading section.

All applications described in the present article use DPP unless otherwise stated.

## Applications

Principal inorganic components detected by polarography are metallic species and certain anions. These applications will be described with respect to periodic elemental groupings. Determination of such analytes have been carried out in a wide variety of sample types such as water (waste and potable), foods (drinks, oils, meat, fruits, vegetables, and cereals), mineral ores, metallurgy, biological fluids (blood, urine), and environmental samples (sediments, soils, aerosols, and natural waters).

The aim of the present article is to highlight which elements are detectable by polarography and the typical detection limits for the applied solution conditions. Enhancement of sensitivity by adsorption (leading to greater analyte concentration at the DME surface, e.g., Si), derivatization (formation of a different electroactive species, e.g.,  $\text{NO}_3^-$ ), catalytic processes (where the product of the electrode process chemically reacts with a nonelectroactive species to regenerate the analyte, e.g., Mo), or combinations of these are illustrated by examples. Where applicable interfering species will be mentioned.

## Groups IA and IIA

Due to the very negative reduction potentials of the elements in these two groups (e.g.,  $E_{\text{red}}$  for potassium lies at around  $-2.9$  V versus SCE) polarographic analysis is not possible in acidic aqueous solutions due to interference by the hydrogen reduction current. In alkaline conditions there is a negative shift of the hydrogen reduction potential and a positive shift in the metal-amalgam reduction potential such that determination is possible. The supporting electrolyte should not react at these extreme potentials; the tetraalkyl ammonium halides generally being the chosen supporting electrolytes. Major cations ( $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Ca}^{2+}$ , and  $\text{Mg}^{2+}$ ) in seawater have been determined by polarography following chemical pretreatment of the sample. However, flame emission spectroscopy would be the preferred technique for alkali and alkali earth metals.

## Group IIIB

Y(III) and Sc(III) yield double reduction currents representing the reduction to the bivalent form and subsequently to the metallic state, although there is little reported polarographic analysis for elements from group IIIB.

## Group IVB

Titanium is reducible from the (IV) oxidation state to the (III) oxidation state, producing a reversible reduction current at  $-0.81$  V versus SCE in  $0.1 \text{ mol l}^{-1}$  HCl, although the reduction potential is shifted greatly with pH changes and addition to the supporting electrolyte of complexing electrolytes such as EDTA, citrate, and tartrate. Titanium has been successfully measured in alloys, steel, minerals, and foodstuffs, having a typical limit of detection of  $5 \times 10^{-8} \text{ mol l}^{-1}$ . Polarographic detection of zirconium, hafnium is not possible.

## Group VB

Vanadium(V) may be determined in ammoniacal electrolyte producing two reduction waves at  $-0.1$  V versus SCE and at  $-1.26$  V versus SCE. Detection limits down to  $10^{-6} \text{ mol l}^{-1}$  have been achieved for vanadium present in petroleum fluids and organic material. Detection limits may be lowered by up to an order of magnitude by catalytic oxidation of the reduced vanadium(V).

Niobium, is electrochemically active in acidic solutions, however, there are few reported polarographic applications. Tantalum has not been determined by polarography.

## Group VIB

Chromium oxidation state discrimination is of major importance, principally owing to the much greater environmental toxicological threat of Cr(VI) compared to Cr(III). Polarography offers the analytical chemist/toxicologist techniques enabling the detection of these two different oxidation states. Cr(VI) and Cr(III) may both be determined electrochemically. Cr(VI) will yield a reduction current in a NaOH solution at around  $-1.5$  V versus SCE. Cr(III), under these solution conditions, is not responsive. However, Cr(III) can be determined after oxidation to Cr(VI), using, for example,  $\text{H}_2\text{O}_2$ , to give the total Cr concentration. Cr(III) is determined by the difference before and after treatment with  $\text{H}_2\text{O}_2$ . However, such an approach may lead to interference from the peroxide reduction current. Alternatively, Cr(III) is electroactive in an acetic acid solution producing a reduction current at about  $-0.8$  V versus SCE. It is therefore possible to measure Cr(VI) after Cr(III) by the chemical reduction of Cr(VI) to Cr(III). The latter approach is subject to interference from the proximity of the Ni and Zn reduction waves. Owing to the toxic nature of Cr(VI) applications have concentrated on biological and environmental samples.

Mo has been determined in soils, rocks, plant materials, and steels. Generally a catalytic reduction wave of Mo(VI), in the presence of nitrate in acidic solution, is monitored (approximately  $-0.13$  V versus Ag/AgCl).

W produces a reduction current at  $-0.2$  V versus Ag/AgCl in acid media representing W(VI) reduction. Detection is possible to  $10^{-6} \text{ mol l}^{-1}$ , below which the reduction of U(VI) may become a source of interference.

## Group VIIB

Mn(II) produces well defined reduction waves in most sample media and has been successfully determined in a wide range of sample types from natural waters to steel samples. Determination is usually carried out in alkaline conditions ( $\text{pH} \sim 9.5$ ), the reduction current appearing at  $-1.55$  V versus SCE. Detection limits are generally of the order of  $10^{-7} \text{ mol l}^{-1}$ . Cr(III), Cr(II), and Fe(II) reduction peaks may, however, be a source of interference. The application of anodic stripping voltammetry (ASV) will lower the detection limits further for Mn.

## Group VIIIB

The determination of Fe(II) at near neutral pH (to prevent hydrogen wave masking) is possible with the

reduction of Fe(II) to Fe metal, being detected at  $-1.4$  V versus SCE (detection limits;  $\sim 10^{-6} \text{ mol l}^{-1}$ ). Fe(III) normally would be too close to the mercury reduction potential, however, with the addition of a complexing agent (e.g., EDTA) and solution  $\text{pH} < 6$ , the reduction potential would be cathodically shifted, enabling differentiation of the oxidation states of iron. Recently Fe(III) has been detected via the reversible reduction of Fe(III) oxinate, preceded by a solvent extraction of the complex in chloroform. Samples analyzed for iron encompass wastewaters, anoxic lake waters, rocks, solar grade silicon, nonferrous alloys, and plant material.

Ni(II) and Co(II) both produce reduction waves ( $-0.8$  and  $-1.2$  V versus SCE, respectively, in ammoniacal solution) and have been determined in chromites, reactor waste, and natural waters. Interferences such as Zn can be minimized by the addition of complexing reagents (e.g., crown ethers), which selectively complex with Ni and Co producing a greater cathodic potential shift compared to the Zn reduction potential. Detection limits using this approach would amount to  $10^{-6} \text{ mol l}^{-1}$ .

Using an ammoniacal/dimethylglyoxime (DMG) media both Ni and Co reduction waves are well resolved from the Zn reduction wave. Additionally, owing to the adsorptive properties of the Ni/Co DMG complex, the limits of detection would be lowered by up to an order of magnitude. Adsorptive stripping voltammetry (anodic and cathodic) would reduce the detection limits even further.

## Group IB

The reduction of Cu(II) occurs typically at  $-0.2$  V versus SCE. Samples analyzed have mainly been potable waters, foodstuffs, soils, and biological samples. Typical limits of detection are of the order of  $10^{-7} \text{ mol l}^{-1}$ . Although the sensitivity may conceivably be enhanced by the presence in the sample solution of an organic ligand, which would form an adsorptive copper complex (e.g., catechol or 8-hydroxyquinoline) analogous to that observed for Ni and Co.

## Group IIB

Zinc and cadmium both exhibit well-defined reduction waves in almost all sample media ( $-1.00$  and  $-0.64$  V versus SCE, respectively, in  $1 \text{ mol l}^{-1}$  KCl solution). Cadmium being perhaps the most quoted example of a reversible electrode process, a detection limit for Cd of  $10^{-8} \text{ mol l}^{-1}$  and  $5 \times 10^{-7} \text{ mol l}^{-1}$  for Zn would be expected. Ni and

Co interference for Zn determinations has already been discussed.

### Group IIIA

The reduction potential of Al(III) is similar to those of the alkali and alkali earth metals making its determination difficult. However, Al may be determined indirectly by measuring an anodically shifted reduction current of an adsorbed di-*o*-hydroxyazo dye complexed with aluminum. The complexed dye would have a different reduction potential compared to the uncomplexed dye.

Recently indium has been detected by DPP following adsorption of the In 1-(2-pyridylazo)-2-naphthol complex on naphthalene in the pH range of 6.5–11.5. The quoted detection limit being  $2 \times 10^{-6} \text{ mol l}^{-1}$ .

### Group IVA

Si has been measured by the formation of the heteropoly acid with Sb(III) and Mo(VI) followed by adsorption onto the DME and is reducible within the DME potential window ( $-0.3 \text{ V}$  versus SCE), with detection limits in the region of  $\sim 10^{-7} \text{ mol l}^{-1}$ .

Reduction of  $\text{Pb}^{2+}$  at the DME is well documented having a characteristic peak potential at  $-0.4 \text{ V}$  versus SCE in  $\text{KNO}_3$  solution (detection limit being  $10^{-7} \text{ mol l}^{-1}$ ). Application of the technique encompasses samples such as rocks, soils, foods, ceramics glass, and biological samples. Recently an alternative approach has been adopted, whereby Pb is complexed with 1-(2-thiazolyazo)-2-naphthol-tetraphenylborate, which is quantitatively retained on microcrystalline naphthalene. Extraction of the Pb complex is carried out using an  $\text{HCl/NaBH}_4$  solution followed by polarographic analysis.

Sn illustrates two reduction processes in a chloride-supporting electrolyte. The first, representing the reduction of Sn(IV) to Sn(II) occurs at  $-0.25 \text{ V}$  versus SCE, followed by the reduction of Sn(II) to the metal (Hg) at  $-0.5 \text{ V}$  versus SCE. Detection limits down to  $10^{-6} \text{ mol l}^{-1}$  would be expected. Organo forms of tin (i.e., dimethyl; trimethyl) have recently been detected in 20% (v/v) methanol/water, tetraethylammonium perchlorate at pH 2.5 by DPP. Detection limits of  $6 \times 10^{-7}$  and  $4 \times 10^{-6} \text{ mol l}^{-1}$  were calculated for dimethyltin and trimethyltin, respectively.

### Group VA

Nitrate and nitrite may be determined by polarography, both anions having significance in the

monitoring of waste and potable waters and for soil analysis. Polarography has a direct advantage over ion-selective electrode (ISE) determination of nitrate as ISE is prone to interferences in high chloride media.

The nitrite and nitrate reduction currents are enhanced in the presence of certain heavy elements such as La(III), Yb(III), U(IV), and Ce(III). Simultaneous determination of nitrate and nitrite is achievable with careful choice of supporting electrolyte. Typical detection limits of  $1 \mu\text{mol l}^{-1}$  are encountered. Interference may arise from sulfate, phosphate, and oxalate.

Nitrite alternatively may be determined via the diazotization with sulfanilic acid followed by the coupling with *N*-(1-naphthyl)ethylenediamine dihydrochloride, detection limits being  $\sim 10^{-7} \text{ mol l}^{-1}$ . Possible enhancement of the sensitivity could be achieved by adsorptive cathodic stripping of this complex.

More recently nitrate has been determined in vegetables by its reduction to nitrous oxide then allowed to react in solution with cobalt(II) and thiocyanate ions, forming an electroactive complex that is reduced at the DME at  $-0.5 \text{ V}$  (versus SCE). The calculated detection limit was 39 mg of nitrate per kilogram of fresh vegetables. The performance of this new approach has been found to be comparable to reference spectrophotometric methods.

Similar to Si, P as orthophosphate may be detected after derivatization with Sb(III) and Mo(VI) of the ternary heteropoly acid which is adsorbed onto the DME (detection limit being  $5 \times 10^{-8} \text{ mol l}^{-1}$ ). Phosphorus determination, like nitrite and nitrate determinations, is of importance for the evaluation of natural, waste, and potable water quality.

Arsenic may occur as different oxidation states, principally as the +5 arsenate and the more toxic +3 arsenite. Arsenite is usually determined in acidic ( $1 \text{ mol l}^{-1} \text{ HCl}$ ) conditions by DPP, two reduction waves appearing at  $-0.4$  and  $-0.85 \text{ V}$  versus SCE, respectively. However, under such conditions the arsenate is not electrochemically active, therefore, arsenate must be reduced to arsenite and then measured polarographically as arsenite (thereby, giving the total arsenic concentration). The detection limit for this approach is of the order of the  $3 \times 10^{-9} \text{ mol l}^{-1}$ . Due to the toxic nature of As compounds, detection is principally carried out in biological and environmental samples.

Sb compounds also exhibit toxic properties, the trivalent form being more toxic than the pentavalent state. Sb(V) is detectable only in strongly acidic solutions in the presence of excess chloride or bromide leading to a double reduction step of Sb(V) to Sb(III), followed by Sb(III) to Sb(Hg). In less acidic solutions

only Sb(III) is electroactive, enabling the possible differentiation of the two oxidation states of Sb (approximate detection limit is  $10^{-7} \text{ mol l}^{-1}$ ).

Recently Bi(III) has been determined in alloy samples by reduction of Bi(III)-oxinate, preceded by its extraction in chloroform (detection limit being  $4.7 \times 10^{-7} \text{ mol l}^{-1}$ ).

## Group VIA

Oxygen is very electrochemically active, such that it is a serious electrochemical interference during the determination of other chemical ion aqueous solutions, hence the necessity for its removal. Principally dissolved oxygen will produce two reduction waves (in alkaline solutions) at the DME. One at around,  $-0.05 \text{ V}$  versus SCE with the production of  $\text{H}_2\text{O}_2$  and the second reduction peak is observable at approximately  $-0.9 \text{ V}$  versus SCE. This property has been capitalized on for the determination of dissolved oxygen, particularly in water (all types), sewage, and physiological applications. However, the traditional DME, although perfectly usable in the laboratory, is not practical when applied in field conditions. Therefore, a membrane-covered sensor is commonly used for fieldwork, encompassing the indicator and reference electrode, separated from the test solution by a gas permeable hydrophobic membrane.

The various oxidation states of sulfur have been determined by polarography applying such techniques to sample types including drinks, wastewaters, petroleum, and environmental samples (anoxic lake waters, sediments/sediment pore waters). Species detected have included  $\text{S}^{2-}$ ,  $\text{SO}_3^{2-}$ ,  $\text{S}_2\text{O}_3^{2-}$ .  $\text{S}^{2-}$  in NaOH solution yields a peak potential around  $-0.75 \text{ V}$  versus SCE. Additions to the solution of acetic acid with subsequent purging will remove  $\text{H}_2\text{S}$ , enabling the detection of  $\text{S}_2\text{O}_3^{2-}$  and  $\text{SO}_3^{2-}$  at respective potentials at  $-0.15$  and  $-0.63 \text{ V}$  versus SCE.

Recently the determination of elemental sulfur and hydrogen sulfide at sub-parts per million levels in petroleum has been achieved by preliminary extraction followed by DPP.

The importance of selenium in biological systems has initiated the application of polarography for its study. Selenium(IV) in acid media will produce two reduction currents one at about  $-0.01 \text{ V}$ , and the other at approximately  $-0.54 \text{ V}$  versus SCE, the first corresponding to the reduction of Se(IV) and the formation of  $\text{HgSe}$ , the second being the reduction of  $\text{HgSe}$  leading to the formation  $\text{Hg}$  and  $\text{Se}^{2-}$ . Using a nitric acid media, detection limits of  $10^{-6} \text{ mol l}^{-1}$  may be achieved. The limit of detection for Se analysis by DPP may be enhanced by the measurement

of the hydrogen catalytic wave. The reduction peak occurs at  $-1.1 \text{ V}$  versus SCE, in the presence of Mo (similar to 100–200 times higher concentrations than Se) at a pH of 1–4.

Te(IV), is reducible in nitric acid ( $\sim 0.25 \text{ mol l}^{-1}$ ) with detection limit of  $\sim 10^{-7} \text{ mol l}^{-1}$ .

## Halogens

The halogens may be determined polarographically by reduction of their halate form (except for chlorate). Bromide, for example, may be determined by DPP after oxidation to the bromate species yielding a cathodic current at  $\sim -1.53 \text{ V}$  versus SCE. The detection limit is  $\sim 1 \times 10^{-6} \text{ mol l}^{-1}$ . Possible interferences would arise from iodate reduction.

Chlorate is not reducible by polarography except in the presence of titanium and molybdenum salts producing a catalytic reduction current, although this technique has a low sensitivity with detection limits being in the order of  $1 \text{ mmol l}^{-1}$ .

Iodate ( $\text{IO}_3^-$ ) may be determined by DPP with detection limits down to  $\sim 2 \times 10^{-8} \text{ mol l}^{-1}$ . Oxidation of the  $\text{I}^-$  in the sample to  $\text{IO}_4^-$  followed by polarographic analysis will allow the determination of the chemical speciation of iodine.

Halides may also be determined by the formation of insoluble mercuric halide salts as a film at the electrode surface followed by the reduction of the film to the metal and the halide.

## Lanthanide Series

Simultaneous determination of Ce, Pr, Nd, Sm, and Eu has recently been carried out in a supporting electrolyte of xylenol orange at pH=4, leading to calculated detection limits in the region of  $10^{-7} \text{ mol l}^{-1}$ .

## Actinide Series

U(VI) has been recently determined by adsorption of the uranium trifluoethylxanthate–cetyltrimethylammonium ion pair complex on microcrystalline naphthalene, in the pH range of 4.2–7.0. A reduction peak would be observed at  $-0.2 \text{ V}$  versus SCE (detection limit being  $1.2 \times 10^{-6} \text{ mol l}^{-1}$ ). The method has been optimized to determine U(VI) in alloys, coal fly ash, biological, synthetic, and wastewater samples.

The above discussion has provided the reader with an overview of polarographic inorganic analyses, emphasizing the flexibility, sensitivity, and limitations of the technique. For more specific information of inorganic applications and recent developments, the reader is referred to references listed in the 'Further Reading' section.

### Introduction

Polarography is probably the only dynamic (electrolytic) electroanalytical technique that can be conveniently and reliably applied for the determination of a wide spectrum of organic compounds. Candidate analytes must typically contain at least one electroactive functional group, which can participate in electrode reactions at potentials within the polarization range of the dropping-mercury electrode (DME). The  $E_{1/2}$  values depend mainly on the nature of the particular electroactive functional group(s), while the rest of the molecule (the size and/or the overall conformation) has only a minor effect on  $E_{1/2}$ . Therefore, it should be stressed that as polarography cannot discriminate between similar organic compounds, such as members of the same homologous series, chromatographic techniques are the methods of choice in these cases.

Organic polarographic analysis is primarily used for the microdetermination of small amounts of a particular electroactive compound in the presence of excess of other nonelectroactive compounds and matrices. It can also be used for the simultaneous determination of mixtures of electroactive compounds with different electroactive groups, under conditions (carrier electrolyte, solvent, and appropriate pH) ensuring wide separation of the corresponding polarographic waves. In the latter case, there must also be no interaction between the product(s) of the electrode reaction of one analyte with the other analyte(s). This article reviews the practical aspects of organic polarography and typical areas of applications.

### Polarographically Active Functional Groups

A functional group of an organic compound is considered to be 'polarographically active' if it can participate in an electrode reaction (thus acting as a depolarizer) at potential values within the polarization range of the DME. The electrode reaction must be fast enough to yield well-developed polarographic waves. In most cases the analyte is reduced during the electrode reaction, resulting in cathodic polarographic waves during a cathodic potential scan. Oxidation reactions are not uncommon creating anodic polarographic waves during anodic potential scans.

Electrochemical oxidation of mercury is also facilitated, taking place at more negative potentials, in the presence of certain organic compounds because of the formation of either soluble complexes or insoluble compounds with mercury. In both cases anodic polarographic waves are obtained during an anodic potential scan allowing the indirect determination of these nonelectroactive compounds.

Typical polarographically active functional groups and the corresponding electrode reactions are shown in Table 1.

### Polarographic Determination of Nonelectroactive Organic Compounds

Organic compounds not containing electroactive functionalities may also be determined polarographically after their quantitative conversion into electroactive species through a suitable reaction. There must also be a convenient route for the separation of the formed species from the excess of the electroactive reagent usually used for this purpose. This conversion may take place in the following ways.

### Introduction

Polarography is probably the only dynamic (electrolytic) electroanalytical technique that can be conveniently and reliably applied for the determination of a wide spectrum of organic compounds. Candidate analytes must typically contain at least one electroactive functional group, which can participate in electrode reactions at potentials within the polarization range of the dropping-mercury electrode (DME). The  $E_{1/2}$  values depend mainly on the nature of the particular electroactive functional group(s), while the rest of the molecule (the size and/or the overall conformation) has only a minor effect on  $E_{1/2}$ . Therefore, it should be stressed that as polarography cannot discriminate between similar organic compounds, such as members of the same homologous series, chromatographic techniques are the methods of choice in these cases.

Organic polarographic analysis is primarily used for the microdetermination of small amounts of a particular electroactive compound in the presence of excess of other nonelectroactive compounds and matrices. It can also be used for the simultaneous determination of mixtures of electroactive compounds with different electroactive groups, under conditions (carrier electrolyte, solvent, and appropriate pH) ensuring wide separation of the corresponding polarographic waves. In the latter case, there must also be no interaction between the product(s) of the electrode reaction of one analyte with the other analyte(s). This article reviews the practical aspects of organic polarography and typical areas of applications.

### Polarographically Active Functional Groups

A functional group of an organic compound is considered to be 'polarographically active' if it can participate in an electrode reaction (thus acting as a depolarizer) at potential values within the polarization range of the DME. The electrode reaction must be fast enough to yield well-developed polarographic waves. In most cases the analyte is reduced during the electrode reaction, resulting in cathodic polarographic waves during a cathodic potential scan. Oxidation reactions are not uncommon creating anodic polarographic waves during anodic potential scans.

Electrochemical oxidation of mercury is also facilitated, taking place at more negative potentials, in the presence of certain organic compounds because of the formation of either soluble complexes or insoluble compounds with mercury. In both cases anodic polarographic waves are obtained during an anodic potential scan allowing the indirect determination of these nonelectroactive compounds.

Typical polarographically active functional groups and the corresponding electrode reactions are shown in Table 1.

### Polarographic Determination of Nonelectroactive Organic Compounds

Organic compounds not containing electroactive functionalities may also be determined polarographically after their quantitative conversion into electroactive species through a suitable reaction. There must also be a convenient route for the separation of the formed species from the excess of the electroactive reagent usually used for this purpose. This conversion may take place in the following ways.

**Table 1** Typical polarographically active organic compounds and the associated electrode reactions

<i>Class of organic compounds</i>	<i>Electrode reaction</i>
<i>Compounds resulting in cathodic waves</i>	
Olefins <sup>a</sup> and polyunsaturated compounds	$\text{RCH}=\text{CHR}' + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{RCH}_2\text{CH}_2\text{R}'$
Halogenated compounds	$\text{RX} + \text{H}^+ + 2\text{e}^- \rightarrow \text{RH} + \text{X}^- \quad (\text{X} = \text{Cl}, \text{Br}, \text{I})$
Aldehydes	$\text{RCHO} + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{RCH}_2\text{OH}$
Ketones	$\text{RCOR}' + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{RCH}(\text{OH})\text{R}'$
Peroxides	$\text{ROOR}' + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{ROH} + \text{R}'\text{OH}$
Epoxides	$\text{RCH}-\underset{\text{O}}{\text{CHR}'} + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{RCH}(\text{OH})\text{CH}_2\text{R}'$
Disulfides	$\text{RSSR}' + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{RSH} + \text{R}'\text{SH}$
Sulfoxides	$\text{RSO}_2\text{R}' + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{RH} + \text{R}'\text{SO}_2\text{H}$
Sulfones	$\text{RSOR}' + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{RSR}' + \text{H}_2\text{O}$
Nitriles	$\text{RCN} + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{RCH}=\text{NH}^{\text{b}}$
Nitroso compounds	$\text{RNO} + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{RNHOH}^{\text{b}}$
Nitro compounds	$\text{RNO}_2 + 4\text{H}^+ + 4\text{e}^- \rightarrow \text{RNHOH} + 2\text{H}_2\text{O}^{\text{b}}$
Hydroxylamines	$\text{RNHOH} + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{RNH}_2 + \text{H}_2\text{O}$
Oximes	$\text{RC}=\text{NOH} + 3\text{H}^+ + 3\text{e}^- \rightarrow \text{RCH}_2\text{NH}_2 + \text{H}_2\text{O}$
Imines	$\text{RCH}=\text{NH} + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{RCH}_2\text{NH}_2$
Diazo compounds	$\text{RN}=\text{NR}' + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{RNHNHR}'$
Aminoxides	$\text{R}_2\text{NO} + 3\text{H}^+ + 3\text{e}^- \rightarrow \text{RNHR} + \text{H}_2\text{O}$
Quinones	$\text{O}=\text{Ar}=\text{O} + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{HO}-\text{Ar}-\text{OH}$
Aryl isothiocyanates	$\text{ArNCS} + 4\text{H}^+ + \text{H}_2\text{O} + 4\text{e}^- \rightarrow \text{ArNH}_2 + \text{HCHO} + \text{H}_2\text{S}$
<i>Compounds resulting in anodic waves</i>	
Amines (aromatic)	$\text{ArNH}_2 \rightarrow \text{oxidation products} + x\text{H}^+ + xe^-^{\text{c}}$
Phenols	$\text{ArOH} \rightarrow \text{oxidation products} + x\text{H}^+ + xe^-^{\text{c}}$
<i>Compounds facilitating oxidation of Hg and resulting in anodic waves</i>	
Thiols (mercaptans)	$2\text{RSH} + \text{Hg} \rightarrow (\text{RS})_2\text{Hg} + 2\text{H}^+ + 2\text{e}^-$
Barbiturates, uracil	$-\text{NHCONH}- + \text{Hg} \rightarrow \text{Hg-complexes} + x\text{H}^+ + xe^-$
Thioureas, thiobarbiturates	$\text{RNHCSNHR}' + \text{Hg} \rightarrow \text{Hg-complexes} + x\text{H}^+ + xe^-$
Complexing reagents L (L = ammonia, amines, aminopolycarboxylates, etc.)	$x\text{L}^{b-} + \text{Hg} \rightarrow [\text{HgL}_x]^{(n-xb)+} + ne^-$

<sup>a</sup> Simple aliphatic olefins are practically nonelectroactive unless activated by conjugation. Fused aromatic rings (naphthalene, biphenyl, anthracene) are also electroactive.

<sup>b</sup> The reaction represents the first reduction step and (depending on the conditions) it can be followed by a second reduction (of the product) step.

<sup>c</sup> The nature of the products depends on the conditions, the number of electroactive groups and their positions. Imines and quinone types of compounds are usually the initial products but polymerization may also take place through free-radical mechanisms.

## Direct Derivatization

A typical example is the nitration reaction:

Nonelectroactive benzene or toluene can be quantitatively converted to electroactive nitroderivatives. The method can be extended to any polarographically inactive but easily nitrated aromatic compounds such as phenols, phenyl-bearing amino acids, and aniline derivatives. Interesting discriminations between similar compounds based on their ability to be nitrated or not can be achieved. Thus, the readily nitrated phenylbarbituric acid (phenobarbital) can be polarographically determined in the presence of a 100-fold excess of diethylbarbituric acid (barbital). The nitration of morphine also provides an excellent route for the polarographic determination of this otherwise practically nonelectroactive alkaloid.

Secondary amines can be converted to electroactive nitrosamines by the action of an excess of nitrous acid:

The polarographically inactive carbon disulfide in alkaline solutions reacts with amines to form electroactive dithiocarbamates:

The same reaction has been exploited for the determination of nonelectroactive amines and amino acids.

## Decomposition

A typical example is the determination of *vic*-glycols or  $\alpha$ -aminoalcohols after their reaction with an excess of periodate (Malaprade reactions) to yield

electroactive aldehydes that are separated from the reaction mixture by distillation:

### Precipitation

A typical example is the determination of organic nitrogen bases (mainly of alkaloids, dyestuffs, and of several pharmaceuticals, e.g., phenothiazine derivatives, antihistaminics, and spasmolytics) after their precipitation with electroactive inorganic anions (such as silicotungstates or  $\text{BiI}_4^-$ ) and appropriate dissolving of the precipitates.

### Practical Considerations

Although the same general principles of polarographic measurements of inorganic species also apply to the polarographic determination of organic compounds, the nature of the electrode reactions involved imposes certain practical problems. These differences and their practical consequences are summarized below.

#### Rate of the Electrode Reactions

Most electrode reactions of inorganic species (e.g., of metal cations) are fast, as far as the electron transfer step is concerned. Hence they are reversible, the limiting currents measured are diffusion controlled and the polarographic waves are well developed, being adequately described by the Heyrovsky–Ilkovic equation. Electrode reactions involving organic species are generally irreversible, noticeable exceptions being those involving quinone–hydroquinone, imino–phenol–aminophenol, and azo–hydrazo redox pairs. Irreversible electrode reactions yield ill-shaped (drawn out) polarographic waves, thus making a wider separation from adjacent waves of other co-existing electroactive species necessary. With irreversible waves  $E_{1/2}$  values vary with the mercury drop time. Hence, it is not generally advisable to use tabulated half-wave potentials for identification purposes.

The rate of electrode reaction is of primary concern when modern pulsed (normal or differential pulse (DP) polarography) a.c. or fast sweep polarographic techniques are used. These techniques are really advantageous when fast electrode reactions are taking place and the observed currents are mainly diffusion limited.

Kinetic waves are common in organic polarography. Carbonyl compounds and carbohydrates result in

kinetic waves because of the slowly established equilibrium between their main form (in water solution) and their electroactive form. In this case temperature effects are more pronounced and the use of thermostated cells is generally recommended for accurate work.

Catalytic waves are of special importance in organic polarography because they result in unusually low detection limits (down to  $10^{-8} \text{ mol l}^{-1}$ ). Many nitrogen-containing compounds (pyridine and quinoline derivatives, many alkaloids) give rise to well-pronounced catalytic waves. Similarly, in the presence of ammoniacal cobalt and nickel solutions, catalytic waves are obtained with sulfur-containing organic compounds (cysteine, dithiopyrimidine, and proteins containing sulfur amino acids).

#### Effect of pH

Contrary to the situation in inorganic polarography, where the complex-formation properties of the supporting electrolyte are of primary concern, in organic polarography the interest is shifted to pH-buffering properties. As a general rule, in all electrode reactions of organic species,  $\text{H}^+$  participates either as a reactant (cathodic reactions) or a product (anodic reactions). Hence,  $E_{1/2}$  values are pH dependent. In the case of the reversible electrode reaction of the general scheme

the dependence of  $E_{1/2}$  on pH is given by the equation

$$E_{1/2} = E^0 - \frac{2.303RT}{n} x\text{pH}$$

Due to the pronounced lack of reversibility of most electrode reactions of organic species, the pH effect is not always predictable, although one should always expect a cathodic (toward more negative values) shift of  $E_{1/2}$  values upon increase of pH. The degree of reversibility of many electrode reactions is also affected by pH. In cases of total irreversibility (e.g., reduction of organic halides)  $E_{1/2}$  values are more or less pH independent. The effect of pH on  $E_{1/2}$  of three pairs of closely related compounds is shown in **Figure 1**.

By controlling pH more efficient separations of the  $E_{1/2}$  values of closely related compounds can be occasionally achieved. Thus, at pH 3 the reduction waves of maleic acid and fumaric acid practically coincide, but at pH 7 the waves are separated sufficiently enough (**Figure 1**) to allow the polarographic determination of maleic acid in the presence of much higher concentrations of fumaric acid.

**Figure 1** Effect of pH on  $E_{1/2}$  values of three pairs of closely related electroactive organic compounds.

Because of the multistep nature of many electrode reactions of organic species, a single analyte may give rise to more than one polarographic wave with different degrees of reversibility. Nitrobenzene in acidic solutions ( $\text{pH} < 4$ ) is reduced in two steps corresponding to the electrode reactions

resulting in two well-separated cathodic waves, the first being about twice as high as the second, indicating the ratio of electrons participating in each half-reaction. In neutral or alkaline solutions a single cathodic wave is obtained, corresponding to the first electrode reaction.

In many cases, the nature of the final product is also pH dependent. Benzaldehyde in alkaline solutions is reduced in a single step according to the electrode reaction

whereas at  $\text{pH} < 2$  a single cathodic wave of half the height also occurs corresponding to the electrode reaction

In intermediate pH values two waves appear with their height ratio dependent on the actual pH.

In many cases the electrode reaction is favored only in a specific pH range, e.g., carbonyl-containing compounds are preferably determined in alkaline solutions because their enolic form is generally reduced more easily than their carbonyl form.

Since  $\text{H}^+$  is consumed during cathodic electrode reactions, or produced during anodic electrode reactions, the pH of the measured solution in the vicinity of the DME (diffusion layer) is expected to be much higher than that of the main bulk of the solution. Therefore, in order to obtain well-developed and reproducible polarographic waves the supporting electrolyte must contain a strong pH-buffer system. Weak buffering may cause drawn out polarographic waves with  $E_{1/2}$  dependent on the analyte concentration.

Interactions of buffer constituents with the analytes are often undesirable, e.g., borate buffers should be avoided with compounds containing vicinal hydroxyl groups, whereas such interactions may be exploited for masking interfering electroactive species in the samples. On the other hand, carbonyl-containing compounds are preferably determined in the presence of excess of ammonia because their imino form yields better shaped polarographic waves.

### Supporting (Carrier) Electrolyte Solvent

Depending on the nature of the analyte or sample, organic polarography may be carried out in aqueous solutions, water-organic solvent mixtures, or pure organic solvents of a protic nature. Commonly used solvents are lower alcohols, dioxane, tetrahydrofuran, dimethylsulfoxide, dimethylformamide, and acetonitrile.

The organic solvent serves the following purposes:

1. It ensures complete dissolution of water-insoluble samples. At concentrations below  $10^{-3} \text{ mol l}^{-1}$ , the analyte may be soluble in water but its matrix components may be water insoluble.
2. By maintaining a low water concentration the DME polarization range increases in the cathodic direction (e.g., up to  $-2.9 \text{ V}$  versus SCE), so the range of possible candidate analytes is enlarged and compounds with reduction waves preceded by the reduction of  $\text{H}^+$  in aqueous solutions can also be determined in purely organic media.
3. The presence of a less protic organic solvent may have a suppressive effect on reducing adsorption phenomena, and hence adsorption prewaves and waves, which in many cases unpredictably complicate the polarograms of organic compounds in real samples.
4. The reversibility of one-electron reductions of compounds with  $\pi$ -electron systems is often enhanced due to stabilization of anion radicals.

The supporting electrolyte must be soluble in the solvent used. Lithium salts ( $\text{LiCl}$ ,  $\text{LiNO}_3$ ) and quaternary ammonium salts ( $\text{R}_4\text{N}^+\text{X}^-$ , where  $\text{R} = \text{CH}_3$  to  $\text{C}_4\text{H}_9$ , and  $\text{X} = \text{Cl}^-$ ,  $\text{Br}^-$ ,  $\text{I}^-$ ,  $\text{ClO}_4^-$ ,

$\text{BF}_4^-$ ,  $\text{PF}_6^-$ ) are extensively used for this purpose. Relatively concentrated solutions are preferable to reduce the pronounced ohmic resistance of the organic solvent and minimize the  $iR$  shifts imposed on observed  $E_{1/2}$  values. Attention should also be paid to the compatibility of the reference electrode used (reference electrodes with nonaqueous internal solutions are available). An electrolyte bridge compatible with both junctions of the electrolyte–solvent solution must separate the reference electrode and the sample solution to prevent clogging of the reference electrode glass frit by precipitation of the internal solution salt.

Deoxygenation of the supporting electrolyte–sample solution must be carried out for relatively extended time periods compared to those required for pure aqueous solutions (e.g., 10–15 min compared to 3–5 min), due to the increased solubility of oxygen in many organic solvents. The inert gas serving this purpose must be saturated in solvent vapor (by passing through washing bottles containing the same supporting electrolyte solution) to prevent evaporation of volatile solvents, which eventually lead to positive analytical errors.

Polarographic data of some representative classes of simple organic compounds are given in **Table 2**. The proximity of  $E_{1/2}$  values of closely related compounds and their dependence on pH are obvious. It should be emphasized that the tabulated  $E_{1/2}$  values are only indicative since in many cases they are strongly dependent on the actual experimental conditions and the DME characteristics.

### Quantification Limit

The quantification limit depends on factors such as: (1) the number of electrons participating in the electrode reaction; (2) the reversibility of the electrode reaction and hence the applicability of modern pulse techniques; (3) the separation of the polarographic wave of the analyte from the waves of other polarographically active compounds – generally a separation of the order of 0.10–0.15 V is adequate provided that well-shaped waves are obtained (a separation of 0.05 V would be enough when DP polarography is used); and (4) factors such as the occurrence of adsorption waves that may distort or totally obscure the polarographic waves.

As a general rule, quantification limits of  $10^{-4} \text{ mol l}^{-1}$  can be readily obtained with conventional (d.c.) polarography, whereas these limits may be reduced to  $10^{-7} \text{ mol l}^{-1}$  or lower by using modern pulse polarographic techniques and particularly square wave (Osteryoung) polarography.

**Figure 2** shows typical polarograms of tetracycline obtained by DP and conventional (d.c.) polarography.

Lower quantification limits (by one to two orders) can be achieved in a limited number of cases by exploiting catalytic polarographic waves, where the concentration of the catalytically active compound is related to the height of the polarographic wave of another species. A typical example is the determination of cystine at concentrations down to  $10^{-7} \text{ mol l}^{-1}$  by its catalytic effect on the reduction wave of  $\text{Co}^{2+}$  (Brdička wave).

### Interferences

Apart from interferences caused by the presence of other electroactive compounds with  $E_{1/2}$  values close to that of the analyte, the most serious problems occur when the samples contain surface-active compounds (e.g., detergents, proteins, water-soluble polymeric compounds used as excipients in drug formulations). Generally, the adsorption of these compounds on the mercury electrode decreases its active surface, hence reducing the electron transfer rate and suppressing the height of the polarographic waves or peaks (in DP polarography). Cases are also known where the polarographic waves are increased. Cathodic shifts of  $E_{1/2}$  values have also been observed upon increasing the concentration of surfactants. This more or less unpredictable action of surfactants makes the use of the standard addition (single or multiple) technique absolutely necessary for quantification purposes.

### Applications

Due to the large number of published applications of organic polarography, only a selected number of determined compounds and of other applications are presented here.

#### Applications in Pharmaceutical Analysis

Organic polarography has its widest range of applications in the analysis and quality control of pharmaceuticals. Literally hundreds of compounds of pharmaceutical importance have been determined polarographically in a broad spectrum of matrices such as pharmaceutical formulations (injections, tablets, ointments, creams, dragées), bulk materials, biological fluids, and extracts. Whereas polarography has been superseded by liquid chromatography as an official analytical technique in the quality control of pharmaceuticals, it is often considered as a complementary technique to ultraviolet–visible spectrophotometry where it can be used as a secondary control.

**Table 2** Polarographic data of some typical simple organic analytes

Compound	Supporting electrolyte	pH	$E_{1/2}$ (V vs. SCE) <sup>a</sup>	$n^b$

<sup>c</sup> Britton–Robinson buffer (acetate–phosphate–borate composite).

<sup>d</sup> The acyclic tautomeric form of the carbohydrate is polarographically active, hence relatively weak kinetic waves only are obtained.

Generally, polarographic determinations, which have an analytical accuracy within the range 1–5%, are more appropriate for measurements of minor constituents of pharmaceutical formulations (typical w/w content <5%). Polarography can also be used for the determination of impurities (typically less than 1%) in bulk pharmaceutical materials. A typical example is the polarographic determination of the by-product ketocompound [I] in commercial lots of chloramphenicol [II]. This determination is of primary importance because of some unwanted physiological side effects of [I]. The polarographic determination of [I] is favored because its cathodic polarographic wave precedes that of chloramphenicol ( $E_{1/2} = -0.75$  V versus SCE at pH 10) by  $\sim 0.15$  V.

Typical compounds of pharmaceutical importance determined polarographically are listed in Table 3.

### Biochemical and Biomedical Applications

Polarographic determinations have been mainly used in clinical chemistry, toxicology, and studies on pharmacokinetics and therapeutic drug monitoring.

Among the very few biochemical applications of polarography the most famous was the 'Brdička protein test'. This test was based on the catalytic double wave (attributed to the –S–S– bonds in peptides and proteins) in ammoniacal solutions containing  $\text{Co}^{2+}$  or  $\text{Co}^{3+}$  salts. This (now obsolete) test provided a fast discrimination between normal sera and those obtained from patients suffering from cancer, and displayed a good correlation between the tumor growth state and the observed polarographic response.

Generally, polarography is not considered as a practical technique for routine clinical analysis.

Typical compounds of biochemical and biomedical importance determined polarographically (most of

(2) Differential pulse polarogram of a  $1\text{ mg l}^{-1}$  solution. (Reprinted from *Analytical Chemistry* September 1972, 44(11): 75A–87A. Published 1972, American Chemical Society.)

them in biological fluids) and other biochemical studies based on polarographic measurements are listed in Table 4.

### Industrial and Agricultural Applications

Organic polarography is extensively used for the determination of compounds of industrial and agricultural interest (particularly for process and quality control). A classic example is the determination of trace impurities (0.001–0.1%) of nitrobenzene in technical-grade aniline.

Polarography has been advantageously used in the dye industry. A variety of intermediates (anthraquinone

**Table 3** Representative compounds of pharmaceutical importance determined polarographically

Alkaloids	Berberine, codeine, dihydrocodeinone, dihydromorphine, heroin, hydroxycodeinone, morphine, quinine, quinone, jervine, lobeline, narceine, pelletierine, piperine, reserpine, strychnine, thebaine, veratramine, veratrosine
Antibiotics	Adriamycin, chloramphenicol, rubomycin, streptomycin, tetracyclines
Barbiturates	Barbituric acid, Phenobarbital, etc.
Benzodiazepines	Chlordiazepoxide, diazepam, flurazepam, lorazepam, medazepam, nitrazepam, oxazepam
Hormones and steroids	Bufagin, convallotoxin, deoxycorticosterone, dienestrol, digitoxin, estrone, flucinolone acetonide, gitoxin, methyltestosterone, pregnenolone-17-ol-3-one, progesterone, strophanthidin, testosterone, thyroxine
Organic nitrates	Glyceryl trinitrate, isosorbite dinitrate, triethanolamine trinitrate (nitranol)
Vitamins:	Vitamin B <sub>1</sub> (thiamine), B <sub>2</sub> (riboflavin), B <sub>6</sub> (pyridoxine), B <sub>12</sub> (cyanocobalamin), C (ascorbic acid), E (tocopherols), folic acid, pantothenic acid, K <sub>1</sub> , K <sub>2</sub> , K <sub>3</sub> (menadione), PP factor (nicotinamide), biotin
Miscellaneous	Benzimidazole drugs, bromoisovalerylurea, cardiazol, chlorhexidine, dicoumarol, dulcin, isoniazid, 2-nitrofur derivatives, parabens (4-hydroxybenzoic acid esters), phenacetin, phenylbutazone (and its metabolite oxyphenbutazone), propiopocaine, quercetin, rutin, thiomersal (sodium ethylmercurithiosalicylate)

**Table 4** Representative biochemical and biomedical determinations and studies by organic polarography

Determinations	Nonprotein sulphhydryl compounds, purines, thiopurines, cystine in the presence of cysteine, cholinesterase and peroxidase activity in blood, nucleic acids, ascorbic acid after $\alpha$ -ray radiation experiments, albumin, heme, hemoglobin, 4-chlorophenylalanine, <i>N</i> -substituted derivatives of nicotinamide, riboflavin in fermentation broths, urea in process streams, activity of BCG vaccine, catecholamines in tissues
General studies	Investigations of the effect of various proteins and of sulfhydryl-type radioprotective drugs on the Brdička wave, interaction of vasopressin and its analogues on native and denatured DNA, transitions of DNA helix coil, electron-transfer studies of various compounds of biochemical interest and proteins, denaturation and renaturation of various proteins, respiration of plant mitochondria, binding of various azo dyes with proteins, radiolysis of ascorbic acid, oxygen uptake by oxidases, dissociation of oxyhemoglobin in blood

**Table 5** Representative applications of organic polarography in industry and agriculture

Dyes	Determination of intermediates in dye synthesis (anthraquinone and derivatives), azo dyes in intermediates, products, coloring solutions and industrial effluents. Determination of aggregation number of textile dyes. Determination of food colors (e.g., of tartrazine type) in soft drinks
Polymers and plastics	Determination of monomers (aldehydes, acrylamide, acrylonitrile, isocyanates, methyl methacrylate, styrene, vinyl acetate) in final products and industrial effluents. Determination of initiators (azodiisobutylnitrile, benzoyl peroxide, cyclohexylperoxydicarbonate, laurylperoxide), inhibitors (hydroquinones, butylated hydroxyanisole, 4- <i>t</i> -butyl phenolsulphide, <i>N</i> -phenyl- $\beta$ -naphthylamine) and organo-tin stabilizers in PVC plastics
Agrochemicals (herbicides, pesticides, fungicides)	Azomethine group ( $>C=N-$ ) containing compounds: cyolane, cytolane, chlordimerform, drazoxolon s-Triazines: atrazine Chlorinated compounds: 2,4-D (2,4-dichlorophenoxyacetic acid), propachlor (2-chloro- <i>N</i> -2-propylacetanilide), pentachlorophenol, picloram (4-amino-3,5,6-trichloropicolinic acid), hexachlorocyclohexane Nitro-group-containing compounds: metaphos ( $\alpha,\alpha$ -dimethyl- $\alpha$ -(4-nitrophenyl) thiophosphate, parathion, paraoxon

and other quinone-type compounds) and final products (azo dyes, e.g., in industrial effluents of dyestuff plants) have been determined polarographically. The aggregation numbers of various textile dyes have been also determined by organic polarography.

The determination of small amounts of monomers, initiators, inhibitors, and stabilizers in plastic products is another field of applications of organic polarography.

Organic polarographic analysis has also been used for the determination of a variety of agrochemicals in various formulations as well as in polluted natural

waters. Determination by DP polarography of metaphos in waters down to  $10^{-8}$ – $10^{-9}$  mol l<sup>-1</sup>, and of parathion and paraoxon in mixtures in the range  $5 \times 10^{-8}$  to  $1 \times 10^{-6}$  mol l<sup>-1</sup> have been reported.

Typical industrial and agricultural applications of organic polarography are listed in Table 5.

## Introduction

Polychlorinated biphenyls (PCBs) are derived from biphenyl by substitution of one to 10 hydrogen atoms by chlorine atoms. Each homolog group has a particular number of isomers: mono-chlorobiphenyl 3, di- 12, tri- 24, tetra- 42, penta- 46, hexa- 42, hepta- 24, octa- 12, nona- 3, and decachlorobiphenyl 1. In total there are 209 possible PCB congeners. A coding system with numbers from 1 (mono-Cl) to 209 (deca-Cl) is normally used for the PCB congeners (chlorobiphenyls or CBs).

PCBs have been produced and used worldwide in large quantities (c. 1.3 million metric tons in total) for many years as transformer oils, cutting oils, hydraulic oils, heat transfer fluids, additives in plastics, dyes and carbonless copying paper, and metal-casting release oils. The production of PCBs was terminated worldwide around the late 1970s to the early 1980s after authorities became aware of the adverse effects of PCBs to the environment, due to their persistency, bioaccumulative properties, and toxicity. Commercial PCB products are produced under the names of Aroclor (USA), Chlophen (Germany), Kanechlor (Japan), Fenclor (Italy), and others.

During the last decade much attention has been paid to the toxicology of PCBs, particularly to the congeners that show the same type of toxicity as polychlorinated dibenzo-*p*-dioxines (PCDDs) and dibenzofurans (PCDFs). Certain PCBs, which lack chlorine substituents in the *ortho*-position, show a particularly high 'dioxin-like' toxicity (enzyme induction through binding of CB to the Ah-receptor),

viz. PCB-77, PCB-126, and PCB-169. Also, mono-*ortho*-substituted CBs show such a type of dioxin-like toxicity, although to a minor extent. The toxicity of dioxin-like CBs is compared to that of the most toxic dioxin, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (2,3,7,8-TCDD) and a toxic equivalency factor (TEF) has been given to those CBs. The TEF value of 2,3,7,8-TCDD is defined as 1.0. These TEF values have been regularly updated according to the most recent information from toxicological studies. The most recent TEF values derived by the World Health Organization (WHO) are given in Table 1. The product of the concentration and the TEF is called the TCDD equivalent (TEQ). The TEQ of all dioxin-like CBs, dioxins and furans together is called total-TEQ.

## Sampling and Sample Pretreatment

PCBs are analyzed in all sorts of environmental matrices: air, seawater, freshwater, sediments, sewage sludge, benthic organisms, fish, marine mammals, human blood, adipose tissue, and others. All samples require a specific approach. Sampling of sediments and biota will be discussed because these belong to the most frequently analyzed matrices in environmental analysis. The analysis of PCBs in water is known to be extremely difficult because their solubility in water is low. Consequently, PCB concentrations in water are extremely low and the analysis is hindered by background contamination. PCB concentrations in air can be determined after sampling by filters or passive sampling systems.

Surface sediments can be collected intertidally or by means of a variety of grab samplers from a vessel. Because PCB concentrations in sediments can show a patchy distribution, several grabs from one location are normally combined to one pooled sediment

sample. Stainless steel materials should be used to avoid contamination from plasticizers such as phthalates. These can interfere in the gas chromatographic (GC) analysis. The grab samplers such as Van Veen sampler normally collect the upper few centimeters of sediment layers. Passive sediment traps can be used to collect samples of material sedimenting through the water column or resuspended from the seabed. In depositional areas, the changing fluxes of PCBs to the

seabed over time can be reconstructed by analysis of dated sediment cores. For this purpose cores of more than a meter in length may be required.

PCB concentrations in biota can vary substantially, particularly at higher levels of the food chain. It is therefore difficult to obtain a representative sample from a certain population. Benthic organisms, shellfish, or fishes are normally pooled to obtain a representative sample and to save expensive analyses of individual samples. PCBs are metabolized relatively slowly, which means that biota samples can be stored at  $-25^{\circ}\text{C}$  for relatively long periods (years) prior to analysis. However, changes in the fat composition may take place at those temperatures, but the influence of those processes on the final result of the PCB analysis is negligible compared to the analytical error. Biota samples can be taken in various ways: benthic organisms can be taken intertidally from rocks or beaches, or sampled by means of a grab dredge or trawl in deeper water. Fish can be taken by rod and line, or in a variety of trawls and other nets depending on the habitat and habits of the species under investigation. Electric fishery techniques are particularly useful for collecting eel samples. Guidelines describing the collection of biota and sediment samples for contaminant analysis have been issued by the Oslo and Paris Commissions.

Sediment samples are transferred to wide-mouthed, solvent-cleaned glass jars for storage in a freezer at  $-25^{\circ}\text{C}$  prior to analysis. The jars should not be overfilled because breakage can easily occur for samples with high-water content. The plastic lids of the jars should be covered inside with solvent-rinsed aluminum foil to avoid the introduction of plasticizers in the sample. Sediment samples can also be dried before analysis, but several procedures carry a risk for the integrity of the samples due to evaporation losses or introduction of interferences or cross-contamination.

Biota samples can be stored in a freezer at  $-25^{\circ}\text{C}$ . The tissues needed for analysis should be removed under appropriate conditions of cleanliness in the laboratory. The glass jars need to be treated in the same way as those used for sediment samples. The samples are normally extracted as wet samples, after drying with, e.g., sodium sulfate. Freeze-drying is not recommended because losses of lower chlorinated CBs can occur. In addition, freeze-drying carries a risk of cross-contamination.

## Extraction

### Soxhlet Extraction

Soxhlet extraction is a simple and effective method. It has been used for a wide range of samples like

soils, sediments, and animal and plant tissues. A wide variety of solvents like dichloromethane (DCM), pure or mixed with acetone or hexane, and acetone-hexane mixtures can be used. The use of nonpolar solvents only is not recommended. The minimum time needed for a regular Soxhlet extraction is normally ~8 hours. Sulfur present in the sediment and soil samples is also extracted, and must be removed by a later cleanup step.

### Solid-Phase Extraction

Solid-phase extraction (SPE) has been used for PCB containing air and water samples. XAD-2 in glass cartridges can be used to collect PCBs from air. XAD-2 can also be used to treat water samples. The amounts of water sampled are usually between a liter and hundreds of liters. This technique puts heavy demands on the cleaning procedure to ensure a low blank from the resin matrix. Column extraction can also be used for fish. After homogenization the sample is ground with anhydrous sodium sulfate ( $\text{Na}_2\text{SO}_4$ ), eventually together with some sand, packed in a chromatography column, and eluted with DCM.

### Supercritical Fluid Extraction

The use of supercritical fluid extraction (SFE) as an extraction technique is related to the unique properties of the supercritical fluid. These fluids have a low viscosity, high diffusion coefficients, low toxicity, and low flammability, all clearly superior to the organic solvents used in SPE extraction. The most common fluid used is carbon dioxide. SFE extractions of sediment samples have shown recoveries of >95% for all the individual PCBs. The separation of PCDDs from PCBs and chlorinated benzenes is difficult because of their similar solubility. An interesting development is the use of fat retainers. Samples, mixed in different weight ratios with, e.g., silica/silver nitrate 10% or basic alumina, can be placed in 7 ml extraction cells. The analytes are recovered by elution with 1.5–1.8 ml of hexane. With the correct fat-silica ratios and SFE conditions, no additional cleanup procedure is necessary for GC with an electron-capture detector (ECD). One drawback of SFE may be that the methods developed are valid for a specific matrix, but as soon as, e.g., the fat content of a biota sample or the type of lipids changes, the method has to be adapted. SFE is relatively complicated compared to other extraction techniques. In addition, the cell volumes are small, which limits the sample intake, and, with that, the detection limits. Finally, some reliable types of SFE equipment have recently been withdrawn from the market. This will have a substantial negative effect on the use of SFE in the near future.

### Pressurized Liquid Extraction

Pressurized liquid extraction (PLE), also called accelerated solvent extraction, has been applied more frequently during the last years. PLE can be used for extraction only, using organic solvents such as toluene or hexane/acetone. Good recoveries may be obtained, but the investment is relatively high (unless the apparatus are self-made). The gain in labor time compared to a simple system such as Soxhlet extraction is limited. However, the use of fat retainers offers the possibility of combining extraction and cleanup. This option leads to considerable savings in labor time, and is very attractive. The fat retainer ratios need to be optimized. Normally, an excess of fat retainer (e.g., silica) is required for achieving good recoveries and quantitative removal of the lipids. This has implications for the sample intake. Larger cells (up to 100 ml) have been introduced recently, which help to overcome possible problems with detection limits. Further developments may include the use of carbon for a selective extraction of dioxin-like PCBs, which would be even more attractive because direct injection of the dioxin-like PCB fraction into the gas chromatograph may be possible.

### Other Extraction Methods

Other extraction methods like (Ultra-Turrax) blending, ultrasonic, and solvent extractions are available. Most of these techniques show good recoveries for specific matrices, and after optimization of the extraction conditions. Microwave assisted extraction is another promising technique. Good recoveries for PCBs have been obtained. The extraction time is short, and samples can be extracted simultaneously. An overview of advantages and disadvantages of the various extraction techniques is given in Table 2.

### Cleanup

Because the amount of lipophilic material in the extract can affect the active surface of the stationary phase and degrade the resolving power of the GC columns, an effective cleanup procedure is essential. Cleanup of extracts can be performed in either a nondestructive or destructive way.

### Nondestructive Lipid Removal

Two methods are available for nondestructive lipid removal: gel permeation chromatography (GPC) and adsorption column chromatography. GPC works according to the principle of size exclusion. Smaller molecules such as PCBs are retained while larger molecules such as fat are eluted earlier. The PCBs in the sample can be isolated in this way from the lipids.

**Table 2** Evaluation of extraction techniques

	Ease of automation	Maximum sample intake	Extraction time	Cost – initial setup	Cost – running expenses	Ease of optimization	Labor time consumption
Soxhlet	Possible	Moderate/large	Moderate	Low	Low/moderate	Easy	Moderate
Blending/ultrasonic	Difficult	Large	Rapid	Moderate	Low	Moderate	High
Chemical modification	Difficult	Large	Slow	Very low	Very low	Moderate	High
Column extraction	Possible	Large	Slow	Low	Low	Difficult	Moderate
Microwave extraction	Difficult	Moderate/large	Rapid	Moderate	Low	Easy	Moderate
PLE	Easy	Moderate/large	Rapid	High	Low	Moderate	Low <sup>a</sup>
SFE	Easy	Small	Rapid	Very high	High	Difficult	Low <sup>a,b</sup>

<sup>a</sup>When combined with fat removal or in another selective way.<sup>b</sup>But high when analyzing samples with a varying composition or lipid content.

With GPC it is difficult to remove ‘all’ the lipids. The remaining traces of lipids have to be removed in a second cleanup procedure, e.g., on an additional silica column or by a second GPC step. Rigid Polymer Laboratories (PL) gels may offer the best result from the current choice of gels. GPC does not separate the PCBs from the other compounds in the same molecular range such as organochlorine pesticides. Therefore, an additional fractionation is often required.

Adsorption column cleanup procedures have been designed to cope with two types of interferences: the coextracted bulk components comprising predominantly lipids and coextracted organochlorine pesticides (described under fractionation). Alumina columns normally provide an excellent cleanup of PCBs from bulk components such as lipids.

### Destructive Lipid Removal

Treatment with sulfuric acid or concentrated base offers an alternative solution for the removal of lipids and other interferences. Because PCBs are generally resistant to sulfuric acid, concentrated sulfuric acid treatment is used for degradation of most aliphatic and many aromatic compounds in environmental samples. Sulfuric acid may affect other compounds such as some halogenated pesticides (e.g., dieldrin) that are determined together with PCBs in one extract.

Lipids can be saponified by heating the extract in a small volume of solvent with 20% ethanolic potassium hydroxide at ~70°C for 30 min. Saponification is not only used for lipids but is also used for the removal of sulfur from sediment extracts. The conditions of saponification are critical. Too high temperatures and too long saponification times can cause decomposition of higher chlorinated compounds such as hexa-deca PCBs, in particular when trace metals are present, e.g., in sediment samples. Metals can act as a catalyst. The chlorine in aromatic meta-ortho CB concentrations as these are normally ~100–1000-fold lower than those of the indicator CBs.

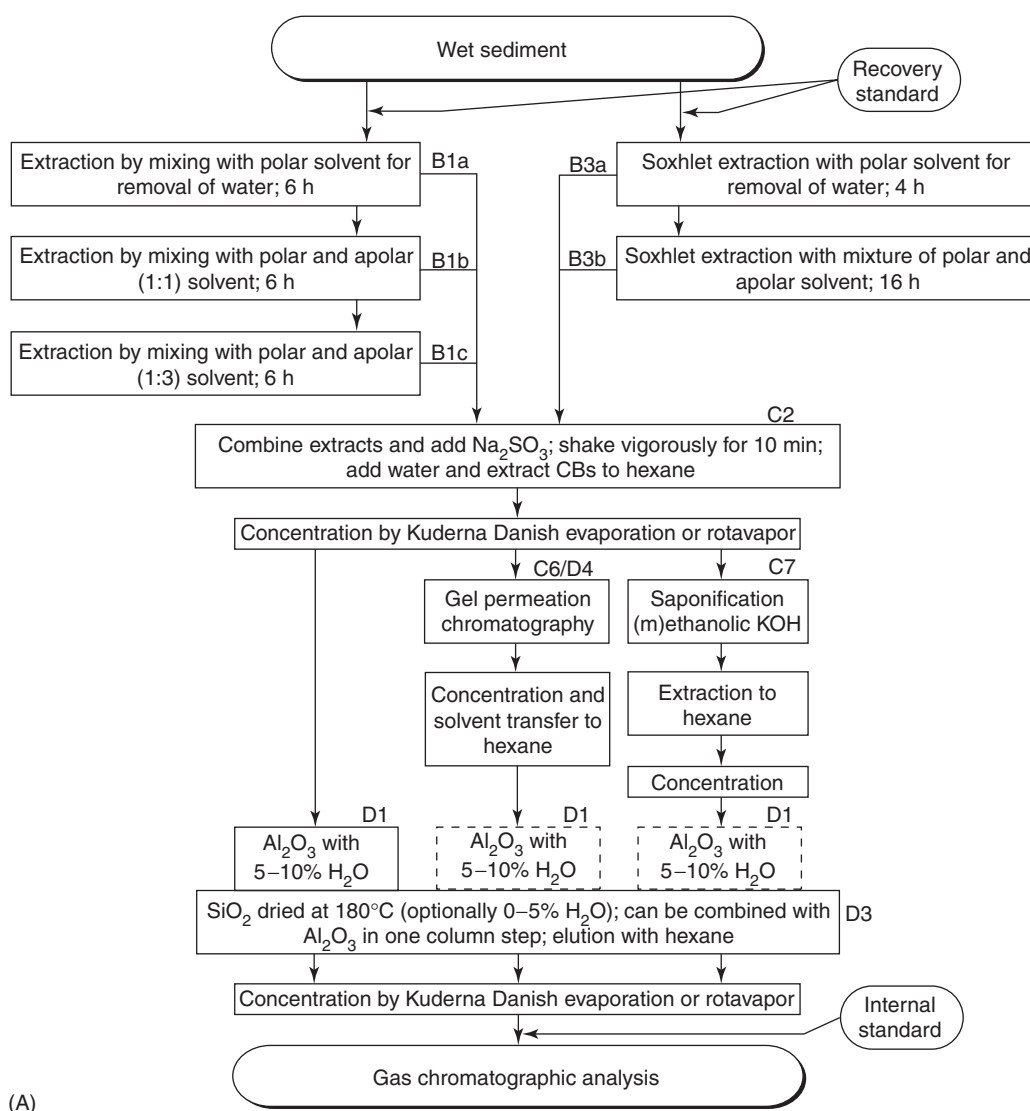

### Prefractionation

PCBs are normally present in the extract after the cleanup together with other halogenated compounds such organochlorine pesticides, brominated biphenyls, and diphenyl ethers. Therefore, it is often important to apply a prefractionation in order to avoid coelution problems. A prefractionation is also required to separate non-*ortho* CBs from the other CBs.

**Adsorption column chromatography** For the cleanup of PCBs in several matrices, alumina, silica, and Florisil columns, in different mesh sizes, levels of activity, and column sizes, can be used. Florisil, a

mixture of several inorganic oxides with  $\text{SiO}_2$  and  $\text{MgO}$  as the main substances, is one of the oldest materials used in the cleanup procedure for PCBs. Because Florisil is a mixture, the composition varies from batch to batch. Silica and alumina have been applied to clean extracts from air, water, sediments, rice bran oil, and animal or human tissue. Preheating and deactivation of the silica with a few per cent of water is necessary. Alumina does not require preheating, but 3–10% of water needs to be added. Disposable silica columns (SPE), precleaned with hexane, can also be used for the cleanup of PCB-containing samples. In Figure 1, a scheme of methods used for the isolation cleanup and fractionation of PCBs in wet and dry sediments is shown.

**Carbon column chromatography (CCC)** CCC exhibits excellent selectivity for those CBs for which a planar conformation is assumed. Different forms of carbon are being used to isolate these congeners. The sorbents used for CCC include activated carbon, activated carbon/polyurethane foam, activated carbon/glass fiber, activated carbon/silica gel, activated carbon/celite, activated carbon/Chromosorb W-HP, and porous graphitic carbon. Activated charcoal is a popular choice, but it has some serious drawbacks such as low efficiency, severe tailing of elution profiles, irreversible adsorption, and large batch-to-batch variations. The use of high-performance liquid chromatography (HPLC) with a porous graphitic carbon column may help to overcome these drawbacks.

**Figure 1** Methods used for the isolation, cleanup, and fractionation of PCBs in (A) wet sediment and (B) dry sediment. (Reprinted with permission from Smedes F and de Boer J (1997) Determination of chlorobiphenyls in sediments – analytical methods. *Trends in Analytical Chemistry* 16: 503–517; © Elsevier.)

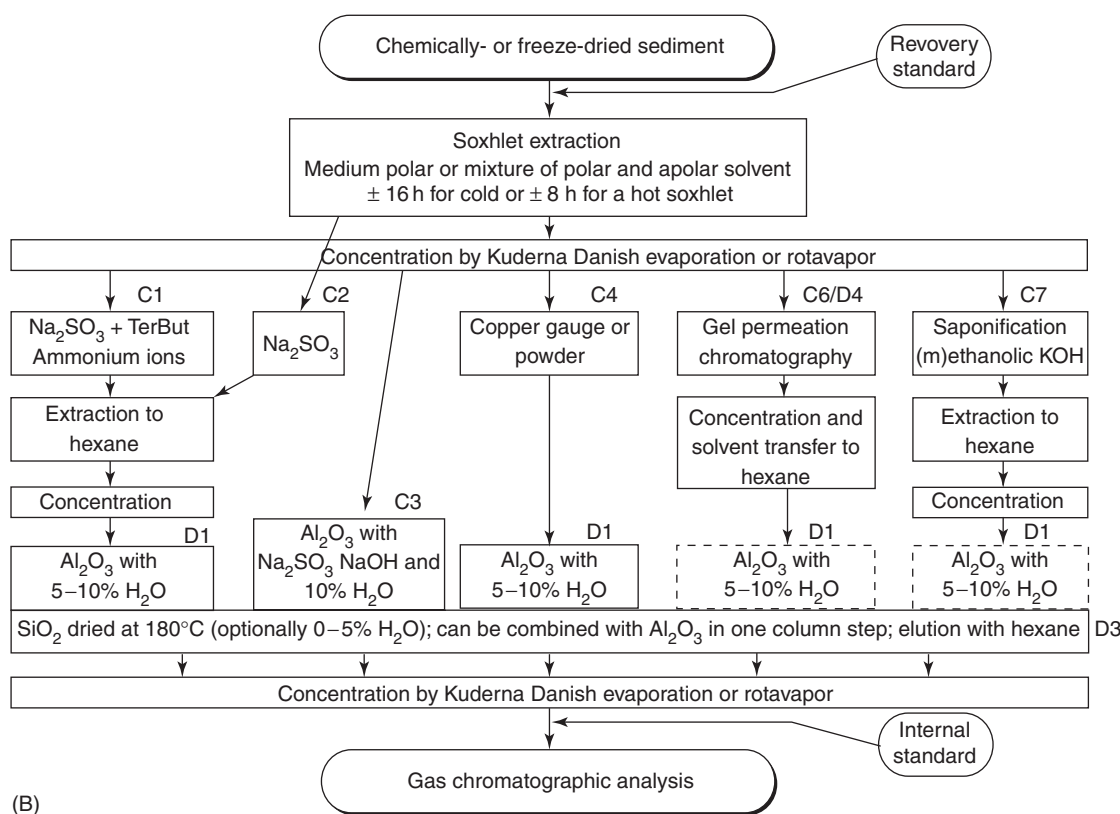

Figure 1 Continued

**Other HPLC columns** The separation of non-*ortho* CBs from *ortho* CBs is also possible by using an electron donor-acceptor HPLC method using a 2-(1-pyrenyl)ethyldimethylsilylated silica (PYE) column. The PYE column separates PCBs according to the number of chlorine atoms in the *ortho* position. The selectivity of the PYE phase may be explained by a charge transfer mechanism, in which electron-density acceptor (EDA) and donor regions of the CBs induce a change in the localization of the  $\pi$ -electron cloud of the pyrene moieties of the phase so that an EDA complex is formed. Separation of the non-*ortho* CBs on a PYE column takes less than 15 min. A 2,4-dinitroanilinopropyl silica (DNAP) phase for the isolation of the non-*ortho* CBs from the other CBs may provide another alternative.

## GC Analysis

PCBs are almost exclusively determined by GC. This is primarily due to the higher sensitivity of the GC detectors, in particular the ECD, as well as to the better separation that can be obtained by GC. Apart from a choice for injection or detection technique in GC, there are many possibilities for the type of columns used, both in single-column GC and in multicolumn approaches.

## Injection Techniques

The most frequently used injection techniques in PCB analysis are splitless and on-column injection. Split injection is not recommended because strong discrimination effects can occur. The presence of high-boiling compounds can increase the effect of discrimination. On-column injection is a technique in which the sample is deposited directly into the column with a syringe. On-column injection is well suited for high-boiling compounds. On-column injection yields better results, but is much more sensitive to contamination than splitless injection. Splitless injection is the most frequently used injection technique. In splitless injection a sample is injected in a hot liner while the splitter is closed. The sample evaporates and enters the GC column. During the time the splitter is closed, the oven is relatively cold, 80–100°C, dependent on the solvent. The ideal temperature is ~10°C below the boiling point of the solvent. After opening the splitter, the oven is rapidly heated and the chromatographic analysis begins. If the liner volume is not large enough, memory effects can occur due to contamination of the gas tubing attached to the injector. Large volume injection is becoming more popular. The increase of the injection volume is directly related to a

decrease of sample intake. Volumes up to 1 ml can be introduced at rates between 1 and 2000  $\mu\text{l min}^{-1}$ . Disadvantages of large volume injection are the stronger influence of solvent impurities in the chromatogram and contamination of the column and detector. Mass spectrometric (MS) detection with negative chemical ionization (NCI) is in particular sensitive for contamination due to large volume injection. A regular cleaning of the ion source may be necessary.

### Detection Techniques

The most frequently used detection system for the analysis of PCBs in various matrices is the ECD. This detector is selective for halogenated compounds. The very high sensitivity of ECD for PCBs theoretically allows detection limits below 1  $\text{ng kg}^{-1}$ . Its extreme sensitivity, on the other hand, makes ECD vulnerable to dirt and overloading. The ECD response varies from one detector to another. The limited linearity is a particular problem. Although linear ranges of several decades are often claimed by manufacturers, in practice the linear range of all ECDs is substantially lower than one decade. Consequently, the use of multilevel calibrations is essential.

The second most frequently used detection system is MS. There are several modes in which the MS is employed to detect PCBs: electron impact (EI) ionization, chemical ionization with negative-ion detection (NCI), or chemical ionization with positive-ion detection (PCI). EI mass spectra are fairly reproducible. They show relatively intense molecular ions and the natural isotopic distribution of chlorine gives rise to typical clusters, which can easily be recognized. The response factors in EI-MS between isomers differ by no more than about twofold, which is much less than in ECD. It is therefore possible to use one surrogate standard within each isomer group. The sensitivity of CBs in NCI increases dramatically with an increase in number of chlorine atoms. The opposite occurs for the CBs determined by PCI. The choice, NCI or PCI, depends on the PCBs to be analyzed, but as most PCBs found in the environment are relatively highly chlorinated, NCI is more often used. Actually, PCI applications for PCB analysis are rather scarce. Absolute detection limits of GC-NCI-MS are  $\sim 100$ , 100, and 50 fg for the CBs 77, 126, and 169, respectively. Compared to GC-ECD, GC-NCI-MS has a more than 10-fold higher sensitivity for CBs with more than four chlorine atoms. EI-MS has a  $\sim 10$ -fold lower sensitivity than ECD. The low environmental concentrations of non- and mono-*ortho* CBs will in general not allow a proper determination by GC-EI-MS. **Figure 2** shows relative response factors (RRFs) of six CBs with a

different number of chlorine atoms for GC-ECD, GC-EI-MS, GC-NCI-MS (total ion chromatogram), and GC-NCI-MS (single ion chromatograms). The highly different NCI signals of CBs with less than five chlorine atoms and higher chlorinated CBs are obvious.

### GC Separation

**Single-column GC** For the analysis of CBs several GC columns can be used. The most frequently used GC column is the SE-54 column (5% diphenyl-1% vinyl dimethyl siloxane). A complete set of retention time data on an SE-54 column is available for all 209 CBs. Other 5% phenyl phases comparable to the SE-54 phase are: CP-Sil-8, DB-5, HP-5, Ultra-2, SE-52, and OV-73. One disadvantage of the SE-54 phase is the number of coeluting PCB congeners: CBs 15/17/18, 28/31, 37/42/59, 47/48/75, 52/73, 66/95, 67/100, 77/110, 82/151, 84/90/101, 87/115, 105/132/153, 114/122/131, 118/123/148/149, 126/129/178, 137/176, 138/158/160/163, 156/171/202, 157/173/201, 170/190, 195/208, and 196/203. Longer columns and smaller diameters may help to resolve some of these congener pairs. A CP-Sil 19 (14% cyanopropyl phenyl-1% vinyl dimethyl siloxane) column offers better possibilities for the separation of the most important PCBs than a SE-54 type column. Comparable phases to CP-Sil-19 are: OV-1701, DB-1701, BP-10, and SFB-7. A single CP-Sil 19 column (85% methyl-7% phenyl-7% cyanopropyl-1% vinyl polysiloxane) offers accurate analyses of 84 congeners by GC-ECD (**Figure 3**). Coelution on a CP-Sil-19 column also occurs: CBs 7/9, 16/29, 17/18, 20/33, 24/27, 32/34, 37/41/64/71, 44/59, 46/49, 55/92, 60/99, 66/95, 81/87/97/115, 82/124/149, 84/119, 107/123, 114/146, 129/183, 132/179, 138/158/160/163/178, 141/176, 144/147, 157/180/197, 169/196/203, 170/190, and 174/200. Other stationary phases used for the analysis of PCB congeners are OV-210 (50% trifluoropropyl methylsiloxane) or comparable phases like QF-1, SP-2401, and RSL-400. Also, 25% phenyl-25% cyanopropyl (OV-225) and comparable phases such as CP-Sil-43, DB-225, BP-15, XE-60, and CS-5 have been used. The highly polar *bis*-cyanopropyl (CP Sil-88) column, commonly used in dioxin analysis has the drawback of a low maximum temperature of 240°C, which increases the analysis time. This phase offers good separation for the most toxic PCBs (77, 126, and 169). None of the stationary phases is able to resolve all 209 congeners in single-column GC. **Table 3** shows the number of separated PCBs on 11 different phases. This table shows that the low bleeding HT-8 column (8% phenyl polycarborane siloxane) offers the best resolution (**Figure 4**).

**Figure 2** Relative response factors (RRF) of six CBs with a different number of chlorine atoms for GC/ECD, GC/EI-MS, and GC/NCI-MS. (Reprinted with permission from Wester PG *et al.* (1995) *Environmental Science and Technology* 30: 473–480; © American Chemical Society.)

**Figure 3** ECD chromatogram of an Aroclor mixture (A1016, A1232, A1248, A1260, 1:1:1:1) on a 50 m x 0.22 mm x 0.26 μm CP Sil 19 column. It is possible to separate the (+) and (–) enantiomers of nine stable atropisomeric CBs (84, 91, 95, 132, 135, 136, 149, 174, and 176) on a Chirasil-Dex (per-methylated  $\beta$ -cyclodextrin) column.

**Multicolumn GC** Multicolumn GC techniques can be divided in parallel column, serial column, and multidimensional (MD) GC. Of these three techniques, MDGC is the most powerful and most frequently used technique.

**Table 3** Number of CBs that can be analyzed with less than 10% interference from any coeluting congener on 11 thoroughly characterized stationary phases<sup>a</sup>

Name	Indicator CBs		Priority CBs		Aroclor CBs	
	MS	ECD	MS	ECD	MS	ECD
ACTYL <sup>b</sup>	6	6	33	31	100	ND
SIL-5	6	5	29	27	102	84
SIL-8	5	5	24	22	81	65

SIL-88	5	2	24	18	99	74

<sup>a</sup> Unless stated otherwise, the temperature program was optimized for a 1 h total run time.

<sup>b</sup> 1.5 h total run time.

<sup>c</sup> 2 h total run time.

Parallel column GC is a method in which two columns are used in parallel and are connected via a glass T-split to a retention gap that is led into the injector. At the other end the columns are each connected to a detector. In this way the PCB analyses can be carried out on two different stationary phases at the same time. An advantage of dual-GC is that only one GC oven, one autosampler, and one injector are necessary.

In serial GC two columns (CP-Sil-8 and HT-5) are coupled in series via a quick-seal glass tube. In this way more separation power can be obtained than with single-column GC, although this depends of the selection of the two columns. The second column may sometimes also destroy separations achieved at the first column. A combination of parallel- and serial-coupled columns is also possible.

The resolving power of capillary gas chromatography can substantially be increased by using MDGC. MDGC can be distinguished in two techniques, heart-cut MDGC and comprehensive MDGC. MDGC is one of the most effective techniques to separate PCBs and to avoid interference from other congeners or other compounds. In heart-cut MDGC normally a nonpolar phase such as SE-54 or CP-Sil-8 is used in the first column to make the initial, well-characterized separation. The column flow is switched by use of a valveless switching technique for the duration of the elution of the peak(s) of interest only to the second column of a different, usually more polar character, preferably installed in an independently controlled oven. This technique offers retention

**Figure 4** ECD chromatogram of an Aroclor mixture (A1016, A1232, A1248, A1260, 1:1:1:1) at an 60 m × 0.25 mm × 0.15 μm HT-8 (1,7-dicarba-closo-dodecarborane phenyl methyl siloxane) column. **Figure 5** Separate heart-cuts of PCBs 60, 74, 114, 123, 157, 167, and 189 from Aroclor 1254; TCN = tetrachloronaphthalene (internal standard). (Reprinted with permission from de Boer *J et al.* (1995) *Analytica Chimica Acta* 300: 155; © Elsevier.)

times with a precision of tenths of seconds. During one run multiple heart-cuts can be made. **Figure 5** shows the chromatograms of the heart-cuts of the seven mono-*ortho*-PCBs of interest present in Aroclor.

The use of a heart-cut technique is relatively laborious when more peaks per run need to be checked for coelution. When the speed of the secondary separation is high enough to separate a cut from the first separation while the next cut is being collected, it is possible to record a complete set of secondary chromatograms. From the secondary chromatograms the complete two-dimensional chromatogram can be constructed. A method capable of doing this is called comprehensive MDGC or GC  $\times$  GC. The heart of the comprehensive MDGC is the modulator of which two basic types are available: thermal modulators and cryogenic modulators. The latter type is meanwhile available in different versions, using either carbon dioxide or nitrogen as cooling agent. The peaks

produced by GC  $\times$  GC are extremely narrow, which improves the sensitivity, but which requires a detector that is able to respond very quickly to the analyte. Flame ionization detection (FID) would be suitable but obviously lacks the sensitivity required for PCB analysis. A micro-ECD is able to handle the GC  $\times$  GC peaks and has enough sensitivity for PCBs. However, an even smaller cell volume would be preferred, as still some peak tailing can be observed. A time-of-flight-MS may be the ideal detector as it couples a high selectivity to a rapid response, and, with the GC  $\times$  GC, with a high sensitivity. An example of a separation of PCBs is given in **Figure 6**. During the last years GC  $\times$  GC has become much more robust and has been used in many different applications. It is expected that software packages for integration will soon be available.

## Quality Assurance

A number of measurements should ensure a sufficient quality of the analysis. Four main areas can be identified: calibrants and calibration, system performance, control of extraction and cleanup, and control of long-term stability.

### Calibrants and Calibration

A CB determination should preferably be carried out using calibration solutions prepared from crystalline, if possible certified CBs. Utmost attention should be paid to the preparation of calibration solutions. Always two independent solutions should be prepared simultaneously. Calibration solutions should preferably be stored in ampoules.

### System Performance

By regularly measuring the resolution of two closely eluting CBs, the performance of the system can be monitored. A decreasing resolution points to deteriorating conditions. The signal-to-noise ratio gives information on the condition of the detector. A dirty ECD detector can be recognized from a higher signal together with a lower signal-to-noise ratio.

### Control of Extraction and Cleanup

For the control of extraction and cleanup it is recommended to let a standard solution pass the whole procedure, from the extraction to the final determination. This standard also gives an indication of the recovery of the sample series.  $^{13}\text{C}$  labeled CBs can be used as internal standards provided MS detection is used. In addition, to all samples and to the standard solution mentioned above, a recovery standard should be added to check whether in

**Figure 6** GC × GC- $\mu$ ECD chromatogram of a mixture of 90 CBs with a HP-1–HT-8 column combination. (Reprinted with permission from Korytar P *et al.* (2002) *Journal of Chromatography A* 958: 203; © Elsevier.)

individual samples losses have occurred. It is recommended that this recovery standard is not used to correct any data, but only for a control on the whole procedure. If major losses have occurred, results should not be reported. CB 29 is suggested as recovery standard. Because of its high volatility, losses due to evaporation are easily detected. CB 29 elutes relatively late from alumina and silica columns. Therefore, also losses due to cleanup may easily be detected with this CB. Small peaks that may be present in the chromatogram at the retention time of CB 29 do not hinder the use of this CB because the recovery standard only controls major errors in extraction or cleanup. It is recommended to use a syringe standard, added in a fixed volume or weight to all standards and sample extracts, to control the final concentration or dilution step and the injection. Appropriate syringe standards are the CBs 29, 112, 155, and 198.

### Long-Term Stability

One internal reference material should be included in each series of samples. This sample should be taken from a large, homogeneous batch of sediment or fish or other frequently analyzed material that can serve as an internal reference material over a long period.

A quality chart should be recorded. In case the warning limits are exceeded, the method used should be checked on possible errors. When the alarm limits are exceeded, the results obtained should not be reported. It is recommended that approximately once each month a certified reference material is analyzed. A laboratory analyzing CBs should take part on a regular basis in interlaboratory studies on the determination of CBs.

## Introduction

Polycyclic aromatic hydrocarbons (PAHs) are a complex class of condensed multinumbered benzenoid-ring compounds (three or more fused benzene rings in linear, angular, or cluster arrangement, which sometimes include a five-membered ring) containing only carbon and hydrogen atoms. Polycyclic aromatic compounds (PACs) include PAHs, and are compounds that have the basic PAH structure and substituent moieties such as alkyl, amino, chloro, cyano, hydroxyl, or thiol groups, and/or containing atoms such as nitrogen, oxygen, or sulfur in the aromatic structure. PACs are ubiquitous environmental pollutants found in air, water, and soil (including sediment). Structures of some PAHs and representative PACs are shown in **Figure 1**. This article will

briefly review the toxicology, sources, and modes of formation of PAHs and the analytical methods used for PAH analysis.

## Toxicology

The potential mutagenic and carcinogenic effects of PAHs are the basic reasons of concern for the levels of these compounds in the environment. The first cancers to be associated with PAH-containing substances were through skin contact that resulted in scrotal cancer of chimney sweeps and skin cancer among mule spinners in the cotton, wool, and jute industries.

Mammals and many lower organisms metabolize PAHs primarily by enzymatic oxygenation to epoxides, phenols, dihydrodiols, quinones, and water-soluble conjugates in an attempt to make them more soluble and thus facilitate their excretion from the organism. In this way, the precarcinogen is converted to the ultimate carcinogen that covalently binds to the information molecules (e.g., DNA, RNA) and leads to carcinogenesis (tumor formation). The biological activity of PAHs is dependent upon molecular structure and thus isomers show diverse carcinogenic activity as shown in **Table 1**. Studies

## Introduction

Polycyclic aromatic hydrocarbons (PAHs) are a complex class of condensed multinumbered benzenoid-ring compounds (three or more fused benzene rings in linear, angular, or cluster arrangement, which sometimes include a five-membered ring) containing only carbon and hydrogen atoms. Polycyclic aromatic compounds (PACs) include PAHs, and are compounds that have the basic PAH structure and substituent moieties such as alkyl, amino, chloro, cyano, hydroxyl, or thiol groups, and/or containing atoms such as nitrogen, oxygen, or sulfur in the aromatic structure. PACs are ubiquitous environmental pollutants found in air, water, and soil (including sediment). Structures of some PAHs and representative PACs are shown in **Figure 1**. This article will

briefly review the toxicology, sources, and modes of formation of PAHs and the analytical methods used for PAH analysis.

## Toxicology

The potential mutagenic and carcinogenic effects of PAHs are the basic reasons of concern for the levels of these compounds in the environment. The first cancers to be associated with PAH-containing substances were through skin contact that resulted in scrotal cancer of chimney sweeps and skin cancer among mule spinners in the cotton, wool, and jute industries.

Mammals and many lower organisms metabolize PAHs primarily by enzymatic oxygenation to epoxides, phenols, dihydrodiols, quinones, and water-soluble conjugates in an attempt to make them more soluble and thus facilitate their excretion from the organism. In this way, the precarcinogen is converted to the ultimate carcinogen that covalently binds to the information molecules (e.g., DNA, RNA) and leads to carcinogenesis (tumor formation). The biological activity of PAHs is dependent upon molecular structure and thus isomers show diverse carcinogenic activity as shown in **Table 1**. Studies

employing animal bioassays have shown that dibenzo[a,b]anthracene, dibenzo[a,b]pyrene, dibenzo[a,l]pyrene, benzo[a]pyrene, benzo[b]fluoranthene, 5-methylchrysene, 7H-dibenzo[c,g]carbazole, 6-nitro-

chrysene, and dinitropyrenes and dinitrofluoranthenes are the strongest carcinogenic PAHs while benzo[fluoranthene]s are moderately carcinogenic.

Though benzo(a)pyrene (BaP) accounts for only a small fraction of the total carcinogenicity of any material or environment (see Table 1), it is the most widely reported and studied PAH. This has been due to its ubiquity and abundance, high carcinogenicity, and relative ease of detectability compared with other carcinogenic PAHs, particularly with luminescence detection. BaP has also been used as an indicator compound for the presence of PAHs.

Relative to other tissues, unmetabolized BaP has been found localized extensively in the mammary gland and body fat after a single feeding of the carcinogen (10–30 mg) to test animals. Minimal tissue localization of BaP and/or its metabolites occurs in the spleen, kidney, lung, and stomach while maximum amounts are recovered from the bile and feces. The level of carcinogen detected in the tissues is also directly related to the dose administered and is dependent on the use of a lipid vehicle. However, owing to the rapid metabolism of PAHs, no significant accumulation takes place in body fat. The amount of PAH excreted in urine is ~20–25% of the amount excreted through feces.

PAHs are metabolized by microsomal mixed-function oxidase systems in conjunction with  $P_{450}$ -type cytochrome enzymes. Various forms of cytochrome  $P_{450}$ -type enzymes are preferentially induced by different PAHs. Isoenzymes belonging to  $P_{450}$  1A,  $P_{450}$  2A,  $P_{450}$  3A, and  $P_{450}$  2B superfamilies are thought to be involved in the metabolism and activation of PAHs. Individually these PAHs also induce enzymatic oxidation to varying degrees and specific inducers stimulate the metabolism of these PAHs differently. This means that some weak carcinogenic or noncarcinogenic PAHs may be potent tumor inducers and may lead to increased amounts of activated metabolites of carcinogenic PAHs. The highest metabolizing

capacity of PAHs is present in the liver followed by the lungs, intestinal mucosa, skin, and kidney.  $P_{450}$  1A related activities in human lung are  $\sim 1\text{--}4\%$  of those in the liver.

One of the activation pathways converting BaP to a highly reactive and probably ultimate carcinogenic metabolite, (+)-7,8-dihydroxy-9,10-oxy-7,8,9,10-tetrahydrobenzo(a)pyrene ((+)-BPDE(1)), is shown in Figure 2. The vicinal (bay-region) diol epoxides are the ultimate mutagenic and carcinogenic species of alternate PAHs. (–)-BPDE(2) and (+)-BPDE(1) bind only weakly with DNA while (+)-BPDE(1), the major product of the enzymatic oxidation reaction, readily decomposes to form a carbonium ion. This

**Figure 2** Enzymatic activation of benzo[a]pyrene.

reacts rapidly with nucleophilic sites in DNA and RNA. In the cellular environment, possible detoxification of (+)BPDE(1) is in competition with its covalent binding to DNA. Both (–)BPDE– and (+)BPDE–deoxyguanosine adducts have been identified in mice and rabbits that have been treated with BaP. The DNA adducts were found to persist in the lung and brain, which could result in their significant accumulation from long-term exposure to low levels of PAHs. Reactions with cellular DNA cause mutation and an eventual loss of the ability to undergo controlled replication.

Nonalternant PAHs, e.g., benzo[fluoranthene], exert their genotoxic effects through their reactive metabolites. Peroxidizing enzyme systems in various body tissues also can form free radicals. These free radicals produced bind to C8 and N7 in guanine and N7 of adenine in DNA. The significance of this pathway for PAHs carcinogenicity has not been evaluated.

Of particular importance and relevance is the presence of PAHs in the atmosphere. At room temperature (20°C), PAHs with more than three aromatic rings have low vapor pressure and therefore will be adsorbed onto particulates. The nature of the particulates either enhances or reduces the cellular uptake of PAH. The following processes are essential to the induction of respiratory tract and lung cancer by airborne PAHs:

1. Retention of the inhaled carcinogenic PAH by the respiratory tract. The PAHs are adsorbed on particulate matter of appropriate size that is inhaled, deposited, and efficiently retained to increase the total exposure level.
2. The deposited PAH is eluted from the particulates by body fluids and taken up in the cell tissues. This process can be facilitated by particles that readily release adsorbed PAHs relative to the rate they are removed from the lungs, or by the presence of those particles that are able to penetrate cell membranes. Particles with aerodynamic diameters ( $<3.5\ \mu\text{m}$ ) may readily reach the pulmonary region of the lungs while larger particles ( $3.5\text{--}10\ \mu\text{m}$ ) are deposited in the nose and tracheobronchial region. Exposure is a function not only of the PAH concentration but also of its distribution between gaseous and particulate phases and among the different sizes of particles with which it is associated.

In the environment, PAHs undergo reactions such as photooxidation, sulfonation, and nitration. These reactions are important not only because they represent a major pathway for the removal of PAHs but also because the reaction products are health hazards themselves and more toxic than the PAHs. Two

examples are the conversions of perylene and pyrene (nonmutagenic) to 3-nitroperylene (directly active mutagen) and 1-nitropyrene (highly mutagenic), respectively. These reactions are influenced by humidity, ultraviolet (UV) radiation, temperature, and the nature of particulates onto which the PAHs are adsorbed. Mutagens may occur in ambient particulates because of the reactions of PAHs with ozone, nitrous oxides, peroxyacetyl nitrate, and free radicals all present to varying degrees in polluted atmospheres.

## Sources

Conditions for the formation of PAHs are most favorable during the pyrolysis of organic matter in air-deficient environments at temperatures in the range 650–900°C. The aromatic compounds formed are more stable than their precursors that include acetylene, butadiene, and butyl benzene.

However, a high temperature is not necessarily required for the aromatization of organic matter. During the formation of crude oil, for example, which takes millions of years, aromatization proceeds in sediments at lower temperatures ( $<150^\circ\text{C}$ ). Also, certain rare organic minerals that fluoresce, e.g., idrialite, pendletonite, and curtisite contain PACs. Other natural sources of PAHs include grassland and forest fires together with volcanic eruptions. The PAH fraction found in young marine sediments is thought to originate largely from forest and grassland fires from which they are dispersed by prevailing winds. Thus, PAHs are found even in remote parts of the world.

PAH emissions from anthropogenic sources account for the largest percentage in terms of annual global input. These sources, which all involve the combustion of organic materials, can be classified as either stationary or mobile (transportation related) processes as illustrated in **Table 2**. The combustion of fossil fuels in the twentieth century is the single most important source of PAHs.

Though tobacco smoking is a minor source of PACs in terms of their total global input, it is of considerable importance with respect to human health. Recent estimates show that ~20% (250 million people) of those living in developed countries will eventually be killed by tobacco-related cancers, e.g., lung and mouth cancers.

The historical diversity and lack of standardization of analytical methods used prior to the 1980s means that the PAH data obtained from diverse environments by different workers prior to the 1980s are difficult to compare. In the 1980s, the availability of

**Table 2** Anthropogenic sources of PAHs

<i>Stationary</i>	<i>Mobile</i>
Industrial processes, e.g., coke production Carbon black production Aluminum plants Asphalt production Petroleum cracking Industrial waste discharge	Gasoline and diesel engines  Land, air, and sea transport Oil spills Tyre wear on roads
Power plants and industrial boilers	
Municipal waste burning and incineration	
Open burning, e.g., coal refuse burning Agricultural waste burning Wild oil well fires Proscribed forest fires	
Residential heating and cooking using fossil and biomass fuels	
Tobacco smoking	

PAH reference materials, as discussed below, has led to standard and widely used methods for PAH analysis. The term 'total PAHs' as used by different researchers has been misleading since there was no universally accepted PAH list. In the 1990s, 16 PAHs listed in the priority pollutants of the US Environment Protection Agency (USEPA) list have been adopted for monitoring in many countries around the world. **Figure 3** shows the structures of the 16 PAHs listed in the priority pollutants of USEPA.

In many cases, reported emission factors have been obtained from a relatively small number of measurements, sometimes only one, and are thus not representative. Emission factors from a particular source will depend on the state of maintenance (e.g., for incinerators, how often the chimneys are scrubbed) and any special measures that have been taken to limit the extent of PAH emission. More PAH data than is presently available is therefore needed for > 90% of all anthropogenic PAH sources in order to

**Figure 3** Molecular structures of PAHs listed in the priority pollutants of USEPA.

accurately estimate the annual PAH global input and the level of human exposure to PAHs.

It is important to pinpoint the PAH source even in an environment where more than one pollutant source is evident. The following source-specific compounds have been used: cyclopenta(*cd*)pyrene for automobile exhaust; benzo(*b*)naphtho(2,1-*d*)thiophene for hard coal combustion; picene derivatives for brown coal combustion, and 1-methyl-7-isopropylphenanthrene (retene) for wood combustion.

## Analytical Methods

Because of the differences in biological activity of PAC isomers, the analytical challenge is to identify and quantify all of the PACs in a particular environment. The task of isomer differentiation is particularly difficult because of the large number of possible isomeric PACs, e.g., the number of possible isomers of unalkylated condensed four-ring PAHs is three, benzo(*a*)anthracene, chrysene, and triphenylene, whereas of unalkylated mononitrobenzo(*a*)anthracene is 12.

The analytical procedure for PAH analysis usually involves sampling, sample preparation techniques, and finally identification and quantification. In environmental samples, PAHs are found in mixtures with wide variation in the relative concentrations of individual components that are at low levels (approximately nanogram per liter). The PAHs are therefore usually concentrated during sampling.

Samples containing PAHs are obtained from air, soil (and sediment), or water so collection procedures to ensure the validity of the sample obtained are very important. For the sample analyzed to represent the 'true' composition of the environmental matrix, sampling must be quantitative, no artifacts should be formed during sample collection, and all sample treatment and storage before analysis must be free from interferences and losses.

During atmospheric PAH sampling, suspended particulate matter is collected on filters while vapor-phase PAHs are collected on solid adsorbents, impregnated filters, polyurethane foam plugs, or liquid impingers. Cryogenic traps and impingers are less popular since they are not sufficiently rugged for field applications.

Water samples are collected in clean glass bottles. If possible, the water should be sampled directly into the extraction vessel and PAHs extracted as soon as possible. If the sample will be stored, then subzero temperatures are used to minimize reactions that lead to loss of PAHs. In the aquatic environment, PAHs are found both dissolved in water and adsorbed on particulates. PAHs are sparingly soluble in water, their solubility decreasing with increasing relative molecular mass. Surface concentration is highest.

Sediment samples (10–100 g) are collected using mechanical grabs, coring devices, or vacuum suction. At low tide, samples are obtained by simply scooping the sediment while water divers use hand coring. Special traps are used for collecting newly deposited sedimentary material.

Birds and eggs are hand collected. Fish and sedentary organisms (e.g., shellfish, oysters, and plankton) are collected at low tide using commercial dredging equipment or nets.

## Sample Extraction and Cleanup

Before proceeding with the chemical analysis, PAHs in the collected samples must be extracted into solution. PAHs are extracted from adsorbents, filters, and solids (including soils and sediments) by Soxhlet extraction, ultrasonic vibration, microwave-assisted solvent extraction, and, more recently, supercritical fluid extraction using a variety of solvents. A disadvantage of Soxhlet extraction is the time taken (6–24 h) while ultrasonic or microwave methods take shorter times, use less solvent volumes, and do not require special glassware. Also pressurized hot solvent extraction in the static, dynamic, and static–dynamic modes give good extraction efficiencies for PAHs. The powerful solvent power and gas-like mass transfer properties of supercritical fluids provide the potential for a rapid and efficient extraction process that results in a concentrated extract (*c.* <1 ml). This may be compared with liquid solvent extractions that take many hours and give a dilute extract (usually more than 50 ml).

Liquid–liquid partition is employed to exhaustively extract PAHs from water using a series of organic solvents. Solid-phase extraction of PAHs is also gaining in usage. In this technique, the aqueous solution is passed through octadecyl- or octyl-bonded silica cartridges to retain organic compounds after which they are selectively eluted with an organic solvent. Fish and biota samples are freeze dried, then mechanically homogenized with an organic solvent such as methanol, acetonitrile, or hexane. Protein-rich samples are saponified with sodium or potassium hydroxide before extraction with an organic solvent.

The liquid extracts of environmental samples contain other organic compounds in addition to PAHs so cleanup procedures must be applied to yield a PAH fraction sufficiently free from extraneous compounds for instrumental analysis. The degree of sample handling and work-up is a function of the sample matrix, extraction method, and solvent, and the instrumental method to be used for the PAH analysis. Aliphatic, polar, and nonpolar fractions of the sample extract are separated by solvent partitioning.

Liquid–solid chromatography at ambient pressure on silica, alumina, or Florisil columns is also used. In this case the polarity of the eluting solvents is gradually changed so that the compounds in the sample are separated on the basis of their polarity. This method has the disadvantages of being slow, having poor reproducibility, requiring manual control, and a new column for every sample and necessitating the use of large quantities of solvents. It is also subject to irreversible adsorption that results in the loss of a percentage of all compounds or, in extreme cases, complete loss of some compounds. Reproducible elution characteristics have been obtained using lipophilic gels, e.g., Sephadex LH-20 and Bio-beads SX-12, in open column liquid chromatographic sample cleanup procedures. Samples have also been separated satisfactorily on thin layer chromatographic plates, the zone containing the PAH fraction being scraped from the plate with subsequent extraction into an organic solvent.

Reversed- and normal-phase preparative liquid chromatography (LC) have both been employed to give reproducible sample cleanup procedures. C<sub>18</sub> prepacked cartridges have gained in popularity because of their speed and reproducible elution properties. Normal-phase preparative LC on polar bonded silica is more popular than reversed-phase preparative LC because the PAH containing aliquots can easily be concentrated by removal of nonpolar solvents at low temperatures. In reversed-phase preparative LC, liquid–liquid extraction of the PAH has to be effected before concentration of the PAH aliquot.

The complexity of the sample dictates the number of isolation steps necessary before the final analysis. For instance, ambient air particulate extracts usually contain predominantly neutral organic compounds that greatly simplify the sample cleanup. In more complex samples, e.g., crude oil, the procedure involves removal of waxes, separation on a silica column, normal-phase preparative LC on an aminosilica column, and elution through a Sephadex LH-20 column.

## Analysis

Even after comprehensive separation and isolation of a PAH fraction from an environmental sample, although it consists mainly of parent PAH (and isomers) and alkyl substituents, it is still likely to be complex and may contain hundreds of compounds spread over wide volatility and concentration ranges. Gas and liquid chromatographic techniques are complementary in the characterization of PAHs in environmental samples. For high molecular mass and nonvolatile PAHs, LC is superior to gas chromatography (GC). High resolution capability of

capillary GC and easy compatibility with mass spectrometers and element specific detectors are strong points in favor of choosing capillary GC over LC for those PACs where both techniques are suitable. However, LC–mass spectrometry (MS) instrumentation has now become more readily available.

## Gas Chromatographic Analysis

Conventional gum phases, methylpolysiloxanes (SE-30, OV-1), 5% phenylmethylpolysiloxane (SE-52), 5% phenyl–95% dimethylpolysiloxane, and 5% phenyl–1% vinylmethylpolysiloxane (SE-54) are popular stationary phases in capillary column GC, by which separation of PAHs up to coronene (relative molecular mass = 300) may be achieved. The stationary phase giving the best separation for a maximum number of PAHs, however, is SE-54 bonded to fused silica capillary columns. It is a slightly more selective stationary phase than SE-30, its selectivity arising from the polarizability of its phenyl groups.

Gas chromatographic separation on gum phases results in the elution of solutes according to their boiling points, which in turn means that isomers having nearly the same boiling points are not separated. Good selectivity and separation of PAH isomers has been achieved using liquid crystal and mesogenic phases, in which the geometry of the molecule is also important. The elution order in an isomeric unsubstituted PAH series follows, in general, the solute length-to-breadth (*l/b*) ratio. The isomer with the larger (*l/b*) ratio is retained longer. Retention of solutes also depends on their strength of interaction with the stationary phase, i.e., the effective surface area of interaction. A planar molecule that can penetrate between the liquid crystals will have a larger interacting surface area than a similar nonplanar PAH that does not penetrate as well.

The flame ionization detector (FID) is the most frequently used detector for PAH analysis in GC. It has a general response character independent of the structure of the hydrocarbon, is reliable, easy to maintain, and has a wide linear range. The photoionization detector (PID) has been used to selectively detect PAHs in the presence of alkanes. The PID has a large linear dynamic range, high sensitivity (100 times that of FID for PAH), and a concentration-dependent response. The electron-capture detector (ECD) is rarely used for PAH detection, mainly because it is necessary to determine response factors for each PAH, it has a low linear range, and shows baseline irregularity when the oven temperature is programmed. The ratio of ECD to FID and FID to PID responses has been used to identify and/or distinguish between different groups of PACs.

The coupling of a mass spectrometer to capillary GC combines an efficient chromatographic separation with high-performance identification. The mass spectrometer can be used as a low-picogram range detector in the total-ion current mode, as a selective detector in the single monitoring mode, or for positive identification to support retention data in the scanning mode. GC-MS is mainly used for identification and confirmation purposes. However, using electron impact ionization, PAH isomers are not easily distinguishable. Positive chemical ionization (CI) with methane, a mixture of methane/argon, or dimethyl ether as reagent can be used to differentiate between PAH isomers. Ion generation using a variable energy ionizing laser in the GC-MS determination of PAHs has shown high sensitivity and selectivity for isomers. A quadrupole mass selective detector employing chemical ionization, electron impact, or fast atom bombardment techniques to give ionization is most commonly used. The amount of data provided by GC-MS during each run (approximately one spectrum every second) makes computerized data acquisition, storage, and processing essential. Computerized data reduction allows subtraction of any spectral background and direct comparison with stored library spectra for identification purposes.

Fourier-transform infrared spectroscopy (FTIR) can be carried out directly by passing the GC eluent through a gold-coated light pipe with IR-transparent windows, or the GC eluent can be frozen on a gold disc and FTIR performed later (matrix-isolation IR). The chromatogram is reconstructed and a plot of chemical-function groups against time produced. Though IR has low sensitivity and resolution, it has the advantage over GC-MS in being able to distinguish between isomers when standard compounds are unavailable. Because gas-phase fluorescence spectra of PAHs are broad and featureless, this method of detection is not very applicable in their analysis by GC.

### Liquid Chromatographic Analysis

Though LC does not approach the separation efficiency of capillary GC, it offers the following advantages:

1. Selectivity can be achieved by changing both the stationary and mobile phases.
2. It can be used for the analysis of compounds that are thermally unstable compounds, e.g., partially condensed molecular structures such as binaphthyl isomers that rearrange to form condensed molecular structures at elevated temperatures.
3. Ultraviolet and luminescence (fluorescence and chemiluminescence) spectrometry provides sensitive and selective detection of PAHs.

A study of a group of alkyl chemically bonded reversed-phase stationary liquids ( $C_6$ - $C_{22}$ ) concluded that  $C_{18}$  provided better PAH separations. With monomeric stationary phases, PAHs are usually separated according to the number of aromatic rings in their chemical structure while with polymeric  $C_{18}$  phases, selective retention of PAH isomers based on the molecular shapes ( $I/b$  ratio) is observed. Phase selectivity of PAHs on polymeric  $C_{18}$  in LC and on smectic liquid crystal phases in GC show close correspondence of retention behavior. PAH specialty columns for separations in LC are now readily available in the market.

Separations of PAH isomers by shape-selective phases are useful if the sample contains compounds within a limited number of aromatic rings, otherwise the sample becomes too complex to analyze because molecules with different ring sizes coelute. This makes identification of the components difficult even when selective fluorescence detectors are used. Multi-dimensional LC should be applied in cases where it is necessary to characterize completely all the components of a complex polyaromatic compound mixture. Normal-phase LC on polar bonded silica gives eluent fractions consisting of molecules with similar numbers of pi-electrons. These can then be further separated on a monomeric-type reversed-phase column into different isomer types. Finally, a shape-selective polymeric  $C_{18}$  reversed-phase column (or liquid crystal column in capillary GC) may be used to separate the specific PAH isomers that differ in planarity and ( $I/b$ ) ratios. Two-dimensional LC is a powerful tool for the separation of PAHs in complex environmental samples because of the higher peak capacity than single column LC.

A major advantage of LC in PAH analysis is the availability of detectors that are highly sensitive and selective to the polyaromatic molecular structure. PAH molecules display strong and characteristic UV absorption, are naturally and strongly fluorescent, and also give sensitized luminescence under peroxyoxalate chemiluminescence (PO-CL) conditions. The high selectivity of fluorescence detection permits the analysis of PAHs in the presence of nonfluorescing compounds. Maximum selectivity and sensitivity can be selected for each compound as it elutes by changing the excitation and emission wavelengths with time (wavelength programming) during the chromatographic run. Therefore, individual PAHs in a mixture can be determined even when complete LC resolution of components has not been achieved. Measurement of fluorescence lifetimes provides the additional information needed to confirm peak assignments based on retention times.

In CL detection, the absence of a light source results in a reduction of the background noise and therefore detection limits are governed by the chemical noise of the system. Usually, a compromise has to be made between the optimum mobile phase for best LC separation and optimum reaction conditions for maximum CL emission. Water, an important solvent in reversed-phase LC, strongly affects the solubility of peroxyoxalate reagents and the kinetics of the PO-CL reaction. However, PO-CL has the potential of being highly selective and sensitive in determining individual PACs as they are eluted in LC, since the CL reactions have high CL quantum yields (>20%) and are highly selective.

MS has been used with LC (moving belt interface), though not as extensively as with GC. Atmospheric pressure chemical ionization and pneumatically assisted electrospray mass spectrometry coupled to LC have been used for PAC analysis. Since it is easy to collect fractions continuously from LC, bioassays of the collected fractions can be performed and a mutachromatogram (a plot of mutagenic potency versus fraction number) obtained.

### Other Analytical Techniques

The potential of supercritical fluid chromatography (SFC) for the analysis of larger relative molecular mass PACs (more than six aromatic rings) using both packed and capillary columns has been realized. SFC provides a higher separation efficiency than LC and good solvation of the larger nonvolatile molecules. However, it has a lower efficiency than capillary GC. FID, UV, fluorescence, and MS have all found application in the detection of PAHs after supercritical fluid chromatographic separation.

Shpol'skii spectrofluorimetry has been used for the determination of PAHs in crude environmental sample extracts with minimum sample cleanup. This technique gives a vibrationally resolved fluorescence spectrum of samples dissolved in a suitable solvent (usually an *n*-alkane) at cryogenic temperatures, e.g., 26 K. It combines the selectivity of an infrared spectrum with the sensitivity of fluorimetry, though the sensitivity suffers considerably from the presence of large amounts of interfering substances such as fatty components in crude extracts since these give a poor-quality matrix with a high sample absorbance.

Recent research has intensified the search for portable instruments for real-time monitoring of airborne PAHs, particularly in the industrial environment. A derivative UV absorption spectrophotometer has been used for real-time monitoring of a small number of aromatic vapors. When synchronous fluorescence and room-temperature phosphorescence (using a

filter paper impregnated with heavy atom salts) are incorporated into automated, continuous air sampling devices, near real-time monitoring of a selected number of PAHs is achieved. Personnel exposure meters to be worn by industrial workers are available. These comprise a filter paper, pretreated with heavy atom salts that enhance the phosphorescence of a selected number of PAHs. The filter holder fits into a phosphorescence spectrometer, allowing fast and direct analysis. A photoelectric aerosol sensor, working on the basis of photoelectric ionization of less than 1  $\mu\text{m}$  induced by UV radiation of a KrBr excimer lamp is used to give the concentration of total PAHs.

### Validation

In GC, correspondence between the retention data of an unknown and a reference compound on two columns of different polarity is considered sufficient for positive identification. Retention indices of PAHs based on naphthalene, phenanthrene, chrysene, and picene are also reliable for identifications. Mass spectral data, though identical for isomers, are invaluable for identification purposes.

Internal standards (IS) are popularly used for the quantitative analysis of PAHs, particularly in methods using capillary GC with FID. This has the advantages of direct measurement of peak area (or height) of solute to peak area of IS, ease of sample cleanup (since what is lost in the sample component is also lost in the IS), and of no necessity to know the exact sample volumes injected. Since the boiling points of PAHs cover a wide range, more than one internal standard for GC analysis is required. Compounds that have been used include 3,6-dimethylphenanthrene for the low relative molecular mass PAHs and benzo(*b*)chrysene or 2,2'-binaphthyl for the higher relative molecular mass PAHs that have longer retention times. Perdeuterated perylene is also used as an internal standard for PAHs during analysis by GC.

Diode array detection of PAHs after LC allows acquisition and storage of each UV spectrum of the eluting peaks. The chromatogram can then be reconstructed at any defined wavelength after the analysis. The spectral output of a diode array is used not only for qualitative and quantitative analysis but also to augment the resolution of chromatographic separation, since poorly resolved components can be identified by deconvolution of the eluent spectra.

Reference standards are essential in the implementation of regulations where limits have been set for PAH concentration levels in various matrices. Many PAHs have been synthesized and highly purified

(>99.9%) and are commercially available. The availability of reference standards helps greatly in the unambiguous identification and reproducible quantification of PAHs in environmental samples.

Certified reference materials are intended primarily for calibration and in quality control of analytical techniques. A certified reference material is a reference material, accompanied by a certificate, one or more of whose property values are certified by a procedure that establishes its traceability to an accurate realization of the unit in which the property values are expressed and for which each certified value is accompanied by an uncertainty at a stated level of confidence. They are used to test, validate, and optimize new analytical techniques as well as in quality control of routine laboratory work. **Table 3** gives a list of environmental samples that provide certified values of PAH content. These are available from various bodies as certified reference materials. In measuring the concentration of a substance for certification purposes, more than two independent and reliable analytical methods are used. Certified reference materials when used for standardization of analytical methods will make comparisons between PAH data obtained by a variety of workers using

different analytical methods possible. Thus, it will be possible to obtain a clear picture of the annual global PAH input and the level of human exposure to these compounds.

## Introduction

Polycyclic aromatic hydrocarbons (PAHs) from anthropogenic sources are discharged into the atmosphere

either in the gaseous state or adsorbed onto particulates. These PAHs are subject to removal mechanisms such as oxidative and photolytic reactions and wet and dry deposition. Air currents and prevailing winds disperse and transport the PAHs over long distances and deposit them on soil and in water. PAHs on soil are carried during storms by water runoff to rivers and seas. In the aquatic environment, the PAHs enter marine plants, fish, and sedentary organisms. PAHs are

thus ubiquitous pollutants that have been detected even in remote parts of the earth, e.g., the average atmospheric concentration of the sum of 11 PAHs at Barrow, Alaska, was reported to be 1.2 and 0.16 ng m<sup>-3</sup> for Mar. and Aug. 1979, respectively, and PAH concentrations in sediments have ranged from undetectable in the Amazon river to greater than 10 000 µg l<sup>-1</sup> in the Charles river, Boston, USA. This article briefly reviews the analysis of PAHs in the atmosphere, water, food, and biological samples.

## Atmosphere

PAHs from all sources where organic matter is burnt (e.g., gasoline and diesel engines, industrial boilers, open burning, etc.) are discharged into the air. At ambient temperatures (20°C), PAHs with up to three rings exist in the gaseous state while those with six or more rings are found exclusively bound to particulates. Four- and five-ring PAHs are found in both gaseous and particulate phases.

The identification and quantitation of airborne PAHs in the ambient air represent a critical aspect in human health assessment. It is therefore necessary to collect both gaseous and particulate bound PAHs. Two sampling trains recommended for general purpose stack sampling of organic compounds with boiling points above 100°C are the modified method 5 and source assessment sampling system with sampling rates of 14–28 and 110–140 l min<sup>-1</sup>, respectively. Both trains have a filter to remove particulates, a cooled sorbent module, and a condensate collector. Samplers operating at flow rates greater than 1.0 m<sup>3</sup> min<sup>-1</sup> (>1000 l min<sup>-1</sup>) have also been used. Isokinetic sampling pumps should be used during both low and high volume samplings.

Glass fiber, quartz, polytetrafluoroethene (PTFE), cellulose acetate membrane, and silver membrane filters have been used for particulate sampling. PAH blanks and losses during sampling, and resistance to airflow should be considered when choosing the filter material. Solid adsorbents that have been investigated for sampling volatile PAHs include charcoal, silica gel, Florisil, molecular sieves, XAD resins (polystyrene-divinylbenzene polymers), Chromosorb 101 and 102, and Tenax GC. Charcoal exhibits poor recovery properties for PAHs while silica gel, Florisil, and molecular sieves show poor moisture tolerance. Chromosorb 101 has a low surface area while Chromosorb 102 has similar properties to XAD-2 but is only available in fine mesh sizes that cause high pressure drops during sampling. When thermal desorption is the chosen extraction method, Tenax GC is preferred because of its high thermal resistance (up

to 375°C). Polyurethane foam is used to trap medium volatile PAHs while XAD-2 resin (used when solvent extraction of PAHs is undertaken) traps the volatile fraction. The Environmental Protection Agency, USA (USEPA) method TO-13 recommends sampling for PAHs in the atmosphere at 230 l min<sup>-1</sup> using QMA quartz filter and XAD-2 resin.

Chemical reactions of organic material collected on filters with other pollutants such as NO<sub>2</sub>, O<sub>3</sub>, HNO<sub>3</sub>, SO<sub>2</sub>, H<sub>2</sub>SO<sub>4</sub>, photooxidation, volatilization during sampling, and sample storage are all ways in which the sample integrity can be violated. Several factors, e.g., sampling face velocity, relative humidity, filter type, and the nature of particulates, may affect volatilization rates and reactions of the trapped PAHs. As sampling times are increased, not only does oxidative degradation occur to PAHs already accumulated on the collection medium, but also sublimation and/or reevaporation processes may take place, resulting in lower quantities of PAHs being trapped. The presence of ultraviolet radiation and oxidants (e.g., sulfur oxides, ozone, nitrous oxides) increases the decomposition rate of PAHs.

Efficient extraction of PAHs from the sample matrix is a crucial step in the preparation of a sample for PAH determination. Knowledge of extraction recoveries allows corrections to be made for PAH quantities not extracted and losses in analytical measurements. Solvent extraction methods, employing Soxhlet, ultrasonic, and supercritical fluid extraction (SFE) procedures are widely used.

PAHs can be Soxhlet extracted from air particulates using solvents such as benzene, toluene, carbon disulfide, dichloromethane, cyclohexane, and methanol for up to 24 h. Methanol is not only efficient in extracting the organic compounds but also extracts a larger amount of inorganic compounds than benzene, toluene, and cyclohexane. Multiple batchwise ultrasonic extractions for 10–60 min are as effective as Soxhlet extraction of PAHs from particulates. Ultrasonic extraction is faster and gives more reproducible extraction than Soxhlet extraction, though a high powered ultrasonicator is more expensive than a Soxhlet apparatus. SFE of PAHs from solid matrices gives comparable PAH extraction efficiencies to Soxhlet extraction but SFE has the advantage of speed (10–60 min) and ease of sample handling. Off- and online techniques may be used to collect the extracted PAHs after depressurization of the supercritical fluid. Though offline SFE is simpler and the extracted sample may be used for various analyses, sample losses may occur due to aerosol formation during depressurization. During online SFE, the extracted analytes are directly transferred to a chromatographic system for analysis.

Because air particulate extracts contain predominantly neutral organic compounds, the sample clean-up procedure is greatly simplified. Polar compounds are removed by partitioning in dimethylformamide/water or in dimethylsulfoxide. Chromatography on a Sephadex LH-20 column separates the aromatic and polar fractions. Normal-phase preparative high-performance liquid chromatography on an amino-bonded silica column with a hexane or heptane mobile phase provides separation of the PAHs based on the number of aromatic carbon atoms in the molecule; aliphatic compounds elute first, then the PAHs in order of increasing ring size, the largest ring compounds eluting last.

The contribution of any PAH source to the ambient air PAH load depends on a number of factors that include emission rate of the source, geographical location, and climatic conditions (e.g., wind strength and direction). Stationary sources account for ~90% of the annual total PAH emissions (estimated total PAH atmospheric emissions for USA, Sweden, and Norway in 1983 were 8600, 500, and 290 tons, respectively). Each year in the USA, ~1.9 million hectares of vegetation land are burnt due to wildfire ignitions in addition to 1.2–2.0 million hectares that are intentionally ignited to achieve land management objectives. Quantitative data are lacking for some mobile sources of PAHs, e.g., from aircraft engines, ships and boats, motorcycles, and lawn mowers. A jet engine has been reported to emit 2–4 mg benzo(a)pyrene (BaP) per minute when cruising and up to 40 000 mg min<sup>-1</sup> during take off. Mobile sources are likely to be the major PAH contributors in areas where major stationary sources are absent. Biomass and coal combustion make an appreciable contribution in areas where they are the dominant energy source, particularly in developing countries. The ratio of methylphenanthrene to phenanthrene is an indicator of the origin of PAHs since a ratio >1 indicates fuel oil contamination, e.g., vehicular exhausts.

Table 1 shows the concentrations of selected PAHs in the ambient air of some cities. PAH emissions exhibit seasonal fluctuations, higher values occurring during the winter due to increase in space heating emissions, lower photochemical activity, and meteorological conditions (e.g., lower temperatures) compared with summer and air mass origin. The profiles of PAHs also differ between and within cities. The levels of PAH in some cities, e.g., Brazzaville (Congo) and Calcutta (India) are due to gasoline and diesel engine exhausts with contributions from biomass combustion sources. The PAH levels in London (and many other European cities) has been decreasing, since peaking (BaP concentration ~100 ng m<sup>-3</sup>) in

the 1960s, through decreasing usage of coal (in both domestic and industrial sectors by replacement with oil and natural gas) and increasing usage of catalytic converters in gasoline engines (starting in the 1980s). Starting from the 1990s, the level of BaP in rural sites in Europe is below  $1.0 \text{ ng m}^{-3}$  while in the urban areas with heavy traffic it is in the range  $1\text{--}10 \text{ ng m}^{-3}$ . In Copenhagen, a mean BaP concentration (Jan.–Mar. 1992) at a petrol station in a busy street was found to be  $4.4 \text{ ng m}^{-3}$ . The reported average total concentration of PAHs (total of 17 PAHs) for two different sites in New York city in 2000 were 3.2 and  $2.9 \text{ ng m}^{-3}$ .

Exhaust emissions from gasoline and diesel engines account for the majority of PAH emissions in urban areas. The emission of PAHs from gasoline engines is affected by factors such as air/fuel ratio, fuel aromaticity, driving mode, oil consumption, cold start, engine design, and the use of alternative fuels, e.g., ethanol and catalytic converters (reduction of BaP emission from  $4.6 \mu\text{g}$  per kg without catalyst to  $0.36 \mu\text{g}$  per kg with catalyst). Diesel engine exhausts may vary in BaP emissions by two orders of magnitude depending on engine design and can give emissions of the same order of magnitude as those from gasoline engines with catalytic converters. Although diesel engine exhausts contain less PAHs than gasoline engine exhausts, diesel emissions are more mutagenic and carcinogenic. This results from the formation of oxygenated and nitro-derivatives of PAHs that occur through reactions between nitrous oxide-rich exhaust and PAH. There has been a worldwide trend to reduce the amounts of lead alkyl antiknock additives in gasoline in order to reduce lead emissions in the atmosphere. In most countries, the octane quality of gasoline with reduced lead content is maintained by increasing the aromatic content, leading to increased PAH emissions.

Currently, there are no national or international standard limits for PAH levels in the environment. The scientific community is in general agreement that it is impossible to formulate a dose (or concentration) of a proven carcinogen or mutagen that is without a residual risk to health. Even the smallest doses of a carcinogen produce some genotoxic damage though no tumor formation is observed during finite experimental conditions. This implies that occupational exposure standards cannot be established. However, industrial hygienists argue that some limit of exposure to carcinogens should be introduced, one reason being that a certain limit is better than none at all. The introduction of occupational exposure limits for carcinogens would have the advantage that the prevailing concentrations would be monitored, with the hope of reducing

exposures to the lowest feasible levels (based on technical, analytical, and economic criteria). Extrapolation of results from laboratory animal inhalation experiments lead to the conclusion that a lifetime exposure to carcinogens in air will result in increased cases of cancer. Human exposure (from ambient air) for BaP is in the range  $<10$  to  $>100 \text{ ng day}^{-1}$ . Additional exposure will result from tobacco smoking and use of unvented heating sources. In the Netherlands, the interim goal is to reduce the annual average air concentration of BaP to  $5 \text{ ng m}^{-3}$  while the USEPA proposes a  $10 \text{ ng m}^{-3}$  guideline level. Poland has set a hygiene standard for BaP in breathing air of  $150 \text{ ng m}^{-3}$ . The United Kingdom has proposed an annual average standard for BaP of  $0.25 \text{ ng m}^{-3}$ . The recommendation by the expert panel on air quality standards (EPAQS) for PAHs is  $0.25 \text{ ng m}^{-3}$ . Reduction of BaP in air will in effect bring down the levels of other PAHs.

## Water

PAHs enter the aquatic environment through offshore drilling activities, oil spills, runoff water, and atmospheric fallout. The water solubility of PAHs decreases with increasing relative molecular mass and molecules with a linear arrangement of fused rings are usually less soluble than those having angular or pericondensed ring systems. Alkyl substituents on the aromatic ring of a given PAH decrease its water solubility. Because PAHs lack polar substituents, they are only sparingly soluble in water and are found mostly adsorbed on suspended particulates and sediment. An equilibrium exists between the PAH dissolved in the water and that adsorbed on particulates, which results in some percentage of even large PAH molecules getting into solution. The presence of organic pollutants, e.g., organic industrial effluents and detergents, influences the solubility of PAHs such that solubility values as high as  $7\text{--}12 \mu\text{g l}^{-1}$  have been reported.

The concentrations of individual PAH in water systems range from less than 1 ppt (pg per g) in pure ground water supplies to greater than 1 ppm ( $\mu\text{g per g}$ ) in heavily contaminated sewage. Therefore, some preconcentration and extraction techniques are required to raise the concentrations to levels at which identification and quantitative analysis are possible. Because PAHs may only represent as little as 0.01% of the total organic fraction present in the water sample, the analytical scheme must be devised so that the PAHs can be analyzed without the interference from the other pollutants. Since the concentrations are so low, serious errors may occur from losses or contamination during sampling or the analytical

process. Any surface with which the sample comes into contact can be a source of contamination or a sink for the trace pollutant. Whenever possible, the sampling should be done directly into the extraction vessel and extracted as soon as possible.

PAH concentrations are highest in the surface film of water. In waters that exhibit turbidity, e.g., rivers and lakes, the PAH will largely be adsorbed on the suspended particulate matter. Analysis of filtered water samples gives lower PAH amounts. Where particulate loading is low, PAHs may be extracted from the unfiltered sample but when particulate loading is high, separate extraction of PAHs from the filtered water and suspended particulate material is more desirable. However, there is the additional problem that PAH loss may occur through adsorption on to the apparatus during filtration.

Water samples should be collected in scrupulously cleaned glass bottles that should be completely filled at the sampling site and stoppers inserted to leave no air space. The screw caps or bottle tops should be PTFE lined or wrapped in aluminum foil and sources of contamination, e.g., dust, motor vehicle exhaust, cigarette smoke avoided. Water samplers have been designed in which a spring-loaded PTFE stopper may be removed and resealed at the sampling depth before recovery of the bottle is undertaken, usually with a rope. During the sampling of surface waters, the use of sampling devices through which the sample flows before entering the sample bottle should be avoided, as they may contaminate or adsorb PAHs. When sampling tap water, the tap should be allowed to flush for at least 2 min unless the first flush samples are specifically required. Residual chlorine must be removed from sampled potable water using sodium thiosulfate. Sampling of the surface film is more involved because of water inclusion and the analytical results are expressed in terms of surface area collected rather than volume collected. The samples are stored in the dark at  $\sim 4^{\circ}\text{C}$  and should be extracted as soon as possible after sampling. An organic solvent, e.g., benzene, is added if the samples are to be stored for several days before extraction. The incorporation of micelles, e.g., polyoxyethylene(*a*)-*p*-nonylphenol, in water samples before storage reduces the rate of loss of PAHs through adsorption onto the container surface. Additionally, the increased solubility of PAHs in the aqueous phase results in the extraction of PAHs from the suspended particulates into the water.

Hydrocarbons are exhaustively extracted using liquid-liquid partition with an organic solvent. Alternatively, the water is passed through a sorbent cartridge, e.g., XAD-2 resin, where the trace organics are retained and the water passes through. The organic compounds are later recovered by elution with a small

volume of organic solvent. This method, compared with liquid-liquid extraction, offers reduced processing times, less labor, and significant saving in glassware and solvent usage. The extraction solvent is dried on sodium sulfate and concentrated in a rotary evaporator. Depending on the concentration levels of other organic compounds that may interfere with the final PAH analysis and the method to be used, it may be necessary to fractionate the sample. Sample cleanup is achieved using column chromatographic techniques.

The concentration levels of PAHs in groundwater and drinking water supplies are of primary concern because a dose-related increase in the incidence of stomach cancer tumors in mice fed on BaP has been reported. The European Community and World Health Organization (WHO) have specified the analysis of six indicator PAHs (fluoranthene, benzo(*b*)fluoranthene, benzo(*k*)fluoranthene, benzo(*a*)pyrene, benzo(*ghi*)perylene, and indeno(1,2,3-*cd*)pyrene) for assessment of the quality of water for human consumption, setting a maximum admissible concentration for the sum of the six PAHs in potable waters of  $200\text{ ng l}^{-1}$  and maximum admissible limit for concentration of BaP at  $0.010\text{ }\mu\text{g l}^{-1}$ . Analysis of water samples obtained from groundwater and drinking water supplies in Germany in 1974 showed that the total concentration of the six indicator PAHs exceeded  $0.11\text{ }\mu\text{g l}^{-1}$  in only 1% of samples and was between  $0.001$  and  $0.01\text{ }\mu\text{g l}^{-1}$  for 90% of the samples. Analysis of water for marine culture in China (Daya bay) for 16 PAHs gave a total of  $4228\text{--}29\,325\text{ ng l}^{-1}$  with BaP concentration at sites as high as  $>10\text{ }\mu\text{g l}^{-1}$ , which can cause acute toxicity. Chlorination of water can remove 50–60% of dissolved BaP while filtration through activated charcoal removes  $>99\%$ . Due to lack of sufficient information, WHO has been unable to set maximum admissible concentrations for individual PAHs except for BaP (maximum admissible concentration of  $0.01\text{ }\mu\text{g l}^{-1}$  was set in 1984). However, methods to reduce the concentration of BaP will result in the reduction of the concentrations of all PAHs. It has been estimated that food accounts for 99% of the daily oral intake of total PAHs with drinking water contributing only 0.1%.

During water distribution, contact with coal-tar-based pipe linings lead to marked increases in PAH concentrations in the water. For this reason, WHO has recommended discontinuation of coal-tar-based pipe lining for drinking water distribution.

## Sediments

Due to their low water solubility and hydrophobic nature, PAHs tend to associate with particulate

matter. Accumulation of PAHs is dependent on sediment type since those with high organic content and smaller particle size (large surface area to volume ratio) have a higher potential to accumulate PAHs compared to coarser sandy sediments. Mussels, which are sedentary, filter feeding, and low-metabolism aquatic organisms, are widely used as sentinels for pollution monitoring of the aquatic environment. They take up and concentrate contaminants to levels above those in the surrounding waters. Particle surface properties and organic matter content are key factors for assessing the bioavailability of PAHs to sedentary organisms. **Table 2** shows a comparison of the total priority USEPA list of PAHs analyzed in water, pore water, sediment, and mussel in different marine sites. In all cases, water has the lowest concentration of PAHs compared with sediments and edible mussel. There is good correlation between BaP and total PAHs ( $r=0.953$ ) for surface sediments. Attempts to replace living organism for measuring contaminants in marine waters with semipermeable membrane devices have been unsuccessful due to different PAH accumulation patterns.

**Table 2** Polycyclic aromatic hydrocarbons in water and sediment in various sites

Location	Matrix	Concentration range

## Food

PAHs have been reported in various types of foods including root and leaf vegetables, vegetable oils, cereals, smoked or grilled fish and meats, roasted foods, and seafood. The source of PAHs in food could either be from the environment or from food preparation or preservation processes. Analysis of PAHs in a food product requires quantitative isolation of the PAH by saponification/digestion in alcoholic potassium hydroxide followed by liquid–liquid extractions, drying over anhydrous sodium sulfate, and cleanup using column chromatographic techniques. For highly insoluble samples, e.g., meats and fish, complete hydrolysis is an absolute necessity. Samples that are highly soluble in hexane or methanol, e.g., oils, are processed directly.

Atmospheric PAHs are deposited on grain foliage, leafy vegetables (e.g., spinach, kale), fruits, and oil plants while PAHs deposited on soil may be absorbed in the roots and translocated to other plant parts. Processing of PAH-contaminated vegetable raw materials gives vegetable oils containing PAHs. PAHs have been reported in soyabean, cottonseed, corn, olive, sunflower, rapeseed, palm, peanut, linseed, and coconut oils. A BaP concentration as high as 43.7 µg per kg in oil from smoke-dried coconut has been reported. Mineral oils and refined petroleum products, which potentially contain PAHs, are ingredients of many cosmetic preparations (e.g., sun-tan oils, cold creams) and medicinal products. To remove the PAHs, oils are treated with activated charcoal.

Smoking, grilling, and the direct heating of foods with air containing combustion gases increases their PAH levels. Products smoked for long periods to blackness have been found to contain high levels of PAHs. During the smoking of food, PAHs on the surface migrate to the interior of food, the extent of migration being dependent on the character of the food product, and its storage time. For example, in smoked bacon, at least 50% of PAHs will be found in the fat drippings. Research into smoked food packaging has shown that cotton fabric and cellophane reduce the PAH content of the smoked meats without removing the smoked flavor and preservative constituents.

PAHs are taken up by both leaves and roots, translocated to other parts of the plant, and may also be concentrated more in certain plant parts than others. Sorghum irrigated with PAH contaminated water has been reported to show an accumulation of fluoranthene and pyrene. The uptake and translocation rates vary with different plant species. The rate (amount per unit time) of PAH uptake by

plants is also dependent on PAH concentration, solubility, phase (vapor or particulate bound), relative molecular mass, and the nature of substrate in which the plant is growing. Analysis of carrots grown on soil containing high levels of PAHs has shown that carrot foliage PAH concentration was unaffected by PAH soil loadings. However, the root peel (<1 mm thick) PAH concentrations increased to a maximum ( $\sim 200 \mu\text{g}$  per kg dry mass for a sum of 14 PAHs) with increasing soil PAH levels, tending to plateau above  $500 \mu\text{g} \sum \text{PAH kg}^{-1}$  (sum of 14 PAHs) in the soil. The carrot core PAH concentrations were significantly lower than peel concentrations. A maximum value of  $38.9 \mu\text{g}$  per kg dry mass of carrot peel for the sum of benzo(*a*)anthracene, chrysene, benzo(*a*)pyrene, and benzo(*ghi*)perylene in the carrots grown on heavily PAH contaminated soils was observed, compared with  $10.7 \mu\text{g}$  per kg dry mass of carrot core for the sum of the same PAHs.

A very low percentage of PAHs in the environment is reported to arise from microbial and plant synthesis. Conversely, some PAH molecules can be catabolized by certain plant species, e.g., anthracene by soyabean. This catabolism is slow and depending on the plant species, transformations of 2–18% of assimilated BaP, mostly to organic acids, over a 14-day period have been reported.

Monitoring of PAHs in a diet is important because of the hypothesis that a correlation exists between a high incidence of gastrointestinal cancers in some populations and levels of PAHs in their diet. PAHs have been found in river and sea sediment, seaweed, and phytoplankton that serve as food for fish and marine filter-feeding bivalves. Values for BaP levels reported in nori, a Japanese seaweed, range from 7.4 to  $31.3 \mu\text{g}$  per kg and benzo(*a*)anthracene in clams purchased from Rhode Island stores (USA) range from 0.1 to  $0.8 \mu\text{g}$  per kg wet mass.

Food can be a major environmental source for PAH exposure to man depending on the geographical location, occupation, lifestyle, and dietary habits. Elevated PAH levels are found in smoked, grilled, and roasted foods. The amounts of these foods consumed vary between regions and therefore some segments of the world population are exposed to high levels of PAHs in the diet. The mean total exposure for a reference man of  $312 \mu\text{g day}^{-1}$  (total PAHs) for a nonsmoker, food contributed 96.2%, air 1.6%, water 0.2%, and soil 0.4%. Smokers get (one pack nonfiltered per day) an additional  $1\text{--}5 \mu\text{g day}^{-1}$ . Most countries do not have maximum acceptable levels of PAHs in foods. In Germany, Austria, and Poland, a limit of  $1 \mu\text{g}$  per kg for BaP in smoked foods must not be exceeded.

## Biological Matrices

PAHs are enzymatically converted in mammalian cells to polar reactive intermediates, capable of covalently binding to cellular macromolecules. This metabolism is complex, involving many steps and enzymes. Most of these intermediate species are converted through secondary metabolic processes in the liver to form inactive products (e.g., glucuronides, sulfates, glutathione conjugates). These are excreted in urine and bile and it is only those products that escape these secondary reactions that react with nucleic acids and proteins, and probably lead to carcinogenesis.

BaP and other PAHs produce liver and lung tumors within half a year following intraperitoneal and subcutaneous injection to new born animals. Skin tumors after dermal application of PAHs to mice provides a background for the initiation/promotion theory in chemical carcinogenesis. BaP is the only PAH that has been tested following inhalation. Long-term inhalation of  $10 \text{ mg BaP per m}^3$  resulted in cancer of the respiratory tract in 35% of golden hamsters.

Many tissues in the human body, including liver, lung, colon, and lymphocytes, have the ability to metabolize BaP. The most important enzymes that mediate the initial oxidation of PAHs in the body are cytochrome P<sub>450</sub> mixed function oxidases (MFOs), which are found in microsomes, nuclei, and mitochondria of cells. MFO enzyme systems function together with NADPH-cytochrome P<sub>450</sub> reductase and require phosphatidylcholine for activity.

Figure 1 shows the principal metabolic pathways of BaP (a representative PAH) and the formation of some conjugates. In the interest of simplicity, further metabolic transformations, such as the P<sub>450</sub> catalyzed oxidation of phenols to phenol-epoxides, conversion of phenols to phenol-dihydrodiols, all the enzymatic steps, and the stereochemistry of the metabolites are omitted.

The principal metabolites formed are arene oxides, which are relatively unstable and are further modified by other enzymes (e.g., epoxide hydrolase (EH) and glutathione-S-transferase (GST)) present in the endoplasmic reticulum. The highest concentration of GST enzymes is found in the liver and most of the glutathione conjugates are preferentially excreted in the bile. In the kidney, glutathione conjugates are biochemically converted to mercapturic oxides, which are excreted in urine. Isomerization of arene oxides, which is assumed to be nonenzymatic (though it can be catalyzed by amino or sulfhydryl groups in proteins) also takes place, resulting in the production of phenols. Single phenolic isomers, in line with theoretical molecular orbital predictions based on the relative stability of the two possible cationic intermediates, are formed predominantly. Further

**Figure 1** Selected metabolic pathways of benzo(a)pyrene. Gluc, glucuronidase; Sulf, sulfatase; R, glucuronate or sulfate; MFO, mixed function oxidases; GST, glutathione-S-transferase; EH, epoxide hydrolase.

oxidation to quinones also takes place. Since the diol epoxides are highly active chemically, they are not normally found among urinary metabolites.

PAH *trans*-dihydrodiols undergo further oxidation, catalyzed by MFOs, to diastereomeric epoxide metabolites. These diol epoxides are poor substrates of EH and undergo nonenzymatic hydration in aqueous media to give tetrol products. The diol epoxide metabolites are principally detoxified through their reaction with glutathione. The phenols, dihydrodiols, and other polar metabolites of PAHs undergo conjugation (mediated by transferase enzymes) with glucuronic and sulfuric acids to form more water-soluble metabolites.

The enzymatic metabolism of PAHs proceeds with high stereoselectivity, giving dihydrodiols with exclusively *trans*-configuration. The principal metabolites isolated for BaP are 4,5-, 7,8-, 9,10-dihydrodiols, 1-, 3-, 7-, 9-phenols, and 1,3-, 1,6-, 6,12-quinones.

An ideal biological monitoring method would permit the direct measurement of PAHs in the target organs. Since routine sampling of tissue from the target organs is impractical, body fluids (mainly urine and blood) are generally used. Unmetabolized BaP has been extracted from urine with dichloromethane, separated by liquid chromatography (LC), and quantified by spectrofluorimetry. C<sub>18</sub> cartridges have also been used for the extraction and concentration of PAHs and metabolites from urine samples. Urinary excretion of BaP and benzo(*a*)anthracene have been found to be significantly higher (>60%) in persons living in highly industrialized areas compared with those living in rural environments. An alternative method is to analyze the urine for specific PAH metabolites that are consistently prominent in environmental samples. The urinary concentration of one metabolite, 1-hydroxypyrene, has been used as a biomarker of PAH exposure. Measurement of metabolites of several PAHs in urine would better

predict occupational exposure. For road paving workers, the level of 1-hydroxypyrene in postshift urine samples has been reported to vary from 0.1 to  $2.8 \mu\text{mol mol}^{-1}$  creatinine. There is a strong correlation between urinary 1-hydroxypyrene and the air concentration of pyrene. Significant correlations have also been observed between urinary 1-hydroxypyrene of coke-oven workers and city residents and levels of pyrene and BaP in ambient air. In another approach, the metabolized PAHs in the urine are reduced back to the parent PAHs by refluxing with hydriodic acid.

Hydrophobic interaction between PAHs and blood serum albumin plays an important role in PAH transportation in the body. Activated carcinogens bind covalently to nucleic acids and proteins and therefore quantitation of the PAH-DNA adduct formed in the body may be used as a measure of the biologically active dose of the metabolically activated PAH. Measurement of the extent of adduct formation of PAHs and their metabolites with haemoglobin in blood samples taken from exposed individuals has been proposed as a marker of the biologically effective dose. Haemoglobin serves as a convenient trapping agent and may be used for assessing the levels of activated carcinogens *in vivo* since it can be obtained in large amounts from red blood cells, and is readily purified and analyzed.

Sensitive immunoassays specific for PAH-DNA adducts allow the detection of one adduct per  $10^6$  nucleotides. Fluorimetry has also been used as an alternative detection method to immunoassays. In another method, isomeric tetrols of PAH are liberated by acid hydrolysis of the DNA-PAH adducts and analyzed by LC with fluorescence detection. Structural studies and detailed characterization of PAH metabolites and their conjugates has been performed by trapping the corresponding fractions at the exit of the LC system. As an example, the total characterization of the *in vitro*-formed benzo(a)pyrenetetrahydrodiol-epoxide-guanosine adduct has been achieved by a combination of nuclear magnetic resonance, circular dichroism, and mass spectroscopic techniques.

In the environment, bacteria that have the ability to degrade PAHs have been reported. Saprotrophic soil fungi *Fusarium solani*, and yeast *Rhodotorula glutinis* metabolize pyrene as a sole source of carbon. Mushroom compost is reported to be used directly to ameliorate phenanthrene contaminated soil. After 111 days incubation time,  $36.7 \pm 2.9\%$  loss of soil-associated phenanthrene was observed. Exposure of

PAHs absorbed on spruce (*Picea abies* (L.) Karst) needles to sunlight irradiation showed photolysis of 18 PAHs under the study to follow first-order kinetics, photolysis half-lives ranging from 15 h for Db(a,b)A to 75 h for phenanthrene.

By detecting and quantitating PAHs and their metabolites in body fluids, and measuring the effective dose of PAH at the cellular level, the amounts of PAH that has actually entered the body (through ingestion, inhalation, and/or skin absorption) can be measured. This will result in a better assessment of human risk associated with exposure to PAH from different environments and a further insight into chemical carcinogenesis.

# POLYMERASE CHAIN REACTION

**J M Wages Jr.**, Palmetto Consulting & Research, Tupelo, MS, USA

© 2005, Elsevier Ltd. All Rights Reserved.

## Introduction

Polymerase chain reaction (PCR) is a technology for exponential amplification of a fragment of DNA. (The PCR is covered by patents owned by Hoffman-La Roche. A license is required to use the PCR process.) The limit of its sensitivity is a single molecule, making PCR a superb qualitative tool for the specific detection of rare DNA sequences. Under proper conditions, the yield of amplified DNA is proportional to the initial number of target molecules, rendering it a quantitative analytical tool as well. Since its original description in 1985, PCR has evolved into an assemblage of varied methodologies almost universally used in basic biological research, biotechnology, clinical research, clinical diagnostics, forensics, food technology, environmental testing, archaeology and anthropology, and other fields. Even though other nucleic acid amplification technologies have been described, PCR remains by far the most widely used.

## Biochemical Basis of PCR

PCR involves the enzymatic synthesis of millions of copies of a specific DNA segment. The exponential amplification of a very small amount of template DNA is achieved using a heat-stable DNA polymerase and an automated heat block that is capable of rapid changes of temperature. The template DNA molecule is initially denatured to two single strands by heating to high temperature (typically 90–95°C) in the first stage of the PCR cycle (**Figure 1A**). Two small oligonucleotides that are complementary to sequences on opposite strands of the template molecule and that flank the DNA segment to be amplified are used as primers for the DNA polymerase. The second stage of the PCR cycle consists of cooling the reaction, which permits the annealing of the single-stranded oligonucleotide primers to the denatured template molecule (**Figure 1B**). The third stage of the reaction is the extension of the new strand from the annealed primer in a 5' to 3' direction by the heat-stable polymerase (**Figure 1C**). This is performed at the optimum temperature for the polymerase (68–72°C). The most commonly used polymerase is the enzyme isolated from *Thermus aquaticus* (*Taq* DNA polymerase). After the first cycle, each template

molecule has been amplified to two molecules. These in turn are denatured in the next cycle and amplified to produce four molecules. The four molecules are amplified to eight in the third cycle, and so on. Each successive cycle effectively doubles the amount of DNA product. The three-stage cycle of denaturation, annealing, and primer extension is repeated 25–40 times in a typical PCR procedure. The product of such a reaction is a large quantity ( $10^{-9}$  to  $10^{-8}$  mol l<sup>-1</sup> in a 10–100 µl volume) of a double-stranded DNA molecule whose length is determined by the distance between the primer sites on the original template molecule. Typically, PCR products or amplicons are 100–3000 bp in length, although much longer (up to ~50 000 bp) amplifications are possible under specific conditions. PCR products are visualized by electrophoresis followed by staining with fluorescent dyes or by hybridization to labeled oligonucleotide probes.

## Technical Aspects of PCR

One of the advantages of PCR technology is the speed and simplicity with which the technique can be performed. A PCR reaction can be set up in a short time, and multiple samples can be handled easily. Components of the amplification reaction (template DNA, DNA polymerase, oligonucleotide primers, buffers) are added to the amplification vessel. The most common containers for PCR are microcentrifuge tubes (0.5–0.2 ml) with thin walls to facilitate rapid heat transfer or multiwell plates (96- or 384-well plates being the most common). Some commercially available systems utilize specially designed vessels such as capillary tubes. The reaction tubes are then placed into an automated programmable thermal cycler for controlled heating and cooling for denaturation, annealing, and extension reactions. Following amplification, some type of DNA sequence analysis is typically performed, although technology for real-time monitoring of amplification obviates the need even to open the PCR tube after cycling is complete.

### Template DNA

One of the advantages of PCR is that DNA from relatively clean samples need not be highly purified to be used as a template for amplification. It is possible to simply heat samples to near boiling to release DNA, then to add the resulting lysate to the PCR reaction tube. Such simplicity is the hallmark of PCR. With some types of biological samples, inhibitors of

**Figure 1** One cycle of a PCR. (A) The template is shown as a double-stranded DNA molecule, which is denatured to two single strands. (B) The short oligonucleotide primers anneal to the complementary regions of the single strands. (C) The polymerase generates a new strand from each single-stranded molecule, creating two double-stranded molecules.

PCR such as heme or polyanionic mucopolysaccharides must be removed by DNA purification.

Virtually any form of DNA can be used as a template in a PCR reaction. Plasmids, cosmids, phagemids, lambda phage, M13 phage, genomic DNA, and many other sources of DNA have all been used successfully. A PCR can be performed directly on colonies or plaques. Although it is possible to amplify a single DNA molecule, a typical PCR reaction uses  $10^5$ – $10^6$  copies of the target DNA as template. In practice, this means adding  $\sim 1 \mu\text{g}$  of eukaryotic genomic DNA, 10 ng of yeast DNA, or 1 ng of bacterial DNA. The concentration of DNA is not critical for most applications, however, and a PCR reaction will work with a wide range of template concentrations.

Often the concentration of template DNA is unknown and does not need to be determined. If necessary, a series of control reactions, each containing a different amount of template, can be performed.

### Biochemical Components

**DNA polymerase** A wide range of DNA polymerases is available for PCR. A cloned heat-stable DNA polymerase from *Thermus aquaticus* (Taq DNA polymerase) is the most commonly used. Other enzymes such as DNA polymerase from *Pyrococcus furiosus* (Pfu DNA polymerase) or *Thermococcus litoralis* (Vent<sup>TM</sup> DNA polymerase, New England Biolabs) have been reported to have a lower error rate

than *Taq* polymerase and may be advantageous for some applications. Typically, 0.5–2.5 units of enzyme are used per 50  $\mu$ l reaction.

**Oligonucleotide primers** Oligonucleotide primers are usually used at a concentration of  $1 \mu\text{mol l}^{-1}$  in PCR reactions (50 pmol per 50  $\mu$ l reaction). Concentrations between 0.1 and  $1 \mu\text{mol l}^{-1}$  can be used. Higher concentrations may increase nonspecific annealing of primers and thus to nonspecific amplification products. PCR primers are normally between 18 and 30 nucleotides in length and should preferably have a guanine + cytosine (G + C) content of  $\sim 50\%$ . The temperature at which half the DNA molecules will be double-stranded,  $T_m$ , in degree celsius, for a primer is estimated by the rule-of-thumb equation:  $2 \times (\text{number of As and Ts}) + 4 \times (\text{number of Gs and Cs})$  (A = adenine, T = thymine). However, more accurate calculation of oligonucleotide  $T_m$  requires consideration of the effects of ionic strength and neighboring bases in the DNA strand (nearest neighbor  $T_m$  calculation methods). Software is available for performing these calculations. The  $T_m$  values for the two primers in a reaction should be similar, and the annealing temperature used is normally  $\sim 5^\circ\text{C}$  below the  $T_m$ . As annealing temperature approaches  $T_m$ , more specific amplifications are achieved, but overall yields may decrease. Despite careful calculations, empirical testing of annealing temperatures is essential for a well-optimized PCR assay. Complementarity at the 3' ends of primer pairs should be avoided as this promotes the formation of primer oligomers (primer dimers). Such artifactual products are themselves templates for PCR amplification and compete with the desired products for deoxynucleotide triphosphates (dNTPs), polymerase, and primers. This leads to a decreased yield of the desired product and the presence of nonspecific products that may complicate analysis.

A primer oligomer forms when two or more primers anneal to each other and are extended during PCR. The double-stranded product acts as a template during subsequent rounds of amplification and competes with the desired product. In general, low annealing temperatures, high enzyme concentrations, and high primer concentrations increase the probability of primer oligomerization. However, it is stringency during the initial cycle of PCR that is most critical for primer oligomer formation, as well as for nonspecific PCR products in general. Various techniques for maintaining high stringency up until the point when primers and enzyme are mixed together have been described (generally called Hot Start). Hot Start methods involve mixing of enzyme and primers only after reactions have reached a

stringent temperature. A simple technique for Hot Start is manual addition of a small volume (typically 5–10  $\mu$ l) of reaction buffer containing the enzyme to the other components maintained in the thermal cycler at  $\sim 80^\circ\text{C}$ , then continuing with standard PCR amplification. Another method involves sealing a portion of the amplification reaction under wax, then adding the remaining reactants above the wax barrier. Enzymatic methods to accomplish the same goal include the use of a modified DNA polymerase that is blocked with a thermolabile group or the use of uracil DNA glycosylase (uracil-N-glycosylase, UNG), deoxyuridine triphosphate (dUTP), and a brief initial incubation at  $50^\circ\text{C}$ . Typically, dUTP is substituted on an equimolar basis for deoxythymidine triphosphate (dTTP) ( $200 \mu\text{mol l}^{-1}$ ), but higher concentrations of dUTP ( $125\text{--}300 \mu\text{mol l}^{-1}$ ) may be beneficial in some assays. Uracil DNA glycosylase is used at 1–2 Units per reaction. This method ensures that any nonspecific product or primer oligomer that is generated during the initial low-stringency conditions will contain uracil (U) and therefore be susceptible to cleavage by UNG. Uracil is excised during the  $50^\circ\text{C}$  incubation, and strand breakage occurs at these abasic sites during the initial denaturation step. In addition to inactivating any contaminating amplicons, this method reduces nonspecific products and primer oligomer. Because residual UNG can degrade the U-containing amplicons, PCR products must be analyzed immediately or stored at  $4^\circ\text{C}$  for short periods of time or frozen for longer times. Alternately, UNG can be removed by extraction with organic solvents or digested with proteases.

The 3' end of a PCR primer should be perfectly complementary to the template DNA. Failure of the 3' end to hybridize results in inefficient amplification. Internal sequences are less critical. Provided a suitable annealing temperature is used, degenerate primers (primers that consist of a pool of different but closely related oligonucleotides) may be used to ensure that primers will anneal to highly variable sequences or sequences that are only partially known. These primers are designed from amino acid sequences or from a comparison of similar genes from other organisms. Sequences at the 5' end of the primer are least critical. Providing the hybridizing portion of the primer is long enough to ensure annealing to the template DNA, nonhomologous 5' extensions (regions that do not correspond to the sequence of the template) can be used to introduce restriction enzyme sites into PCR products to be cloned or to add other sequences such as phage RNA polymerase promoters.

Multiplex PCR enables the detection of multiple gene sequences within the same reaction. Because several sets of PCR primers must function in the

same reaction without interference, primer design and optimization of reaction conditions are critical.

Primers are often labeled with detectable groups to facilitate post-PCR analysis. Radioactive isotopes, haptens such as biotin, or fluorescent dyes are the most widely used. Labels attached to the 5' end of a primer have little or no effect on amplification.

Many heat-stable polymerases used for PCR exhibit a template-independent activity that adds deoxynucleosides (predominantly deoxyadenosine) to the 3' ends of all double-stranded molecules in the reaction. These A-overhangs must be filled in prior to blunt-end cloning of PCR products. Alternatively, special vectors are available that have single 3' T-overhangs at the cloning site ready for insertion of the PCR product. Choosing a polymerase without this activity or adjusting reaction conditions to either minimize or maximize the extent of A-overhangs may produce sharper peaks in high-resolution electrophoretic analysis.

**Deoxynucleoside triphosphates** dNTPs are typically used at a concentration of  $\sim 200 \mu\text{mol l}^{-1}$  each dNTP in a PCR reaction. Excessively high concentrations promote nonspecific product formation. Modified dNTPs are sometimes used to label PCR products with radioactive or fluorescent markers or with haptens such as biotin, fluorescein, or digoxigenin. The modified dNTP is typically used at a concentration ( $0.1\text{--}1 \mu\text{mol l}^{-1}$ ) much lower than the unmodified dNTP ( $\sim 200 \mu\text{mol l}^{-1}$ ). Probes can be easily generated using PCR amplification with a labeled nucleotide, followed by removal of the unincorporated label.

**Buffer components** Several reagents containing buffer ions, monovalent salts, and divalent cations required for polymerase activity, have been described for use in PCR amplification. The most widely used buffer consists of  $10 \text{ mmol l}^{-1}$  Tris-HCl (pH 8.3 at room temperature) and  $50 \text{ mmol l}^{-1}$  KCl. At the extension temperature ( $72^\circ\text{C}$ ), the pH of this Tris buffer falls to 7.2, near the optimum for *Taq* DNA polymerase. Sulfate-containing buffers such as  $20 \text{ mmol l}^{-1}$  Tris- $\text{SO}_4$  (pH 8.5–9.0 at room temperature) and  $20 \text{ mmol l}^{-1}$   $(\text{NH}_4)_2\text{SO}_4$  are also widely used. Monovalent cations ( $\text{K}^+$  or  $\text{NH}_4^+$ ) are included to adjust ionic strength. DNA polymerases require divalent cations for activity, and PCR reactions contain  $\text{MgCl}_2$  ( $1\text{--}5 \text{ mmol l}^{-1}$ ). In general, higher  $\text{MgCl}_2$  concentrations promote nonspecific primer annealing and nonspecific product amplification. Reaction buffers usually include a low percentage (0.1–0.5%) of nonionic detergent such as Igepal CA-630, Tween 20, or Triton X-100 to minimize adsorption of polymerase to the surfaces of the PCR tube.

Proteins (gelatin or bovine serum albumin) are sometimes included at similar concentrations as nonionic detergents for the same reason. Other components that have been reported to increase PCR product yields or specificity on specific templates include betaine, dimethylsulfoxide, formamide, and glycerol.

### Thermal Cycling Equipment

The PCR process involves thermal cycling between denaturation, annealing, and extension temperatures (Figure 1). Each incubation step is a segment, and a complete round of denaturation, annealing, and extension is a cycle. First, samples are heated to a temperature adequate to melt the double-stranded DNA template and any secondary structure in the primers. Denaturation is most commonly performed at  $94^\circ\text{C}$ , although temperatures of  $97\text{--}99^\circ\text{C}$  may be required for templates with high GC content. After the first several cycles, denaturation temperature can be lowered to  $90\text{--}92^\circ\text{C}$  to reduce loss of polymerase activity through heat denaturation during the course of PCR. Next, samples are cooled to an annealing temperature at which the primers will hybridize to their target sequences. The choice of annealing temperature depends on primer  $T_m$ , but is usually in the range of  $50\text{--}60^\circ\text{C}$ . Finally, the samples are heated to the extension temperature ( $68\text{--}72^\circ\text{C}$ ). If primers are designed to permit efficient annealing at  $60\text{--}68^\circ\text{C}$ , the annealing and extension steps can be combined into one step. Typical PCR amplification is performed over 20–30 cycles, although 40 or more cycles may be used with template DNA at very low initial concentration or with otherwise marginal amplifications involving, for example, degenerate primers or poor-quality template DNA.

Although it is possible to perform 20 or even 40 cycles of PCR manually using sandbaths, waterbaths, or heat blocks and physically moving the samples from one to the other at timed intervals, the tedium involved makes this approach impractical. Many different types of machines are commercially available to perform thermal cycling. Some cyclers use robotic arms to transfer a rack of PCR samples from one heat block to another. Other machines use resistive heating elements, compressors, water circulators, fan-forced air, high-intensity lamps, Peltier elements, or combinations of these heating and cooling devices. Microprocessors enable the user to program the instrument for time and temperature of each segment, and the number of cycles to be performed.

Thermal cyclers that can monitor progress of the amplification reaction while it is taking place are called real-time thermal cyclers. Real-time instruments are designed to monitor fluorescence from labels whose emission intensity is proportional to the

amount of amplified DNA. Flexibility varies greatly among the available machines, but all instruments can measure fluorescence at least once during the annealing segment of every cycle. Intercalating dyes such as ethidium bromide or SYBR Green that are selective for double-stranded DNA provide the simplest method. Probes that hybridize adjacent to one another on one strand of the amplicon can be designed to have a fluorescence energy transfer donor and acceptor that will be close enough for energy transfer if and only if hybridization occurs. Emission from the hybridized donor- and acceptor-labeled probes is monitored during each cycle. A third approach is to use the 5' nuclease activity of *Taq* DNA polymerase to cleave a probe labeled with a fluorophore and a quencher. When *Taq* DNA polymerase (and some, but not all, other heat-stable polymerases) encounters the probe, it cuts it, dissociating the fluorophore and quencher. As with energy transfer methods, amplification is detectable as an increase in fluorescence. In addition to monitoring fluorescence, real-time thermal cyclers provide data analysis for quantitation of initial template concentration. Real-time PCR has become the standard for quantitative PCR.

### Post-PCR Analysis

Unless real-time thermal cyclers are used, some form of manipulation or analysis of PCR products must be performed. In preparative applications, amplicons are inserted into a suitable vector and propagated by standard molecular biological methods. In analytical applications, some form of DNA size or sequence analysis is performed. In many cases, high-performance liquid chromatography or electrophoresis on agarose or polyacrylamide gels to confirm that the amplicon is the expected size is sufficient. In clinical testing, hybridization of an oligonucleotide probe complementary to a sequence between the PCR primers is more commonly used to confirm specificity of the amplified DNA. Probe hybridization can be combined with DNA size analysis by electrophoresis or can be performed using methods analogous to immunoassays.

## Considerations

### Fidelity

For preparative applications and the analysis of single-base changes, fidelity of the DNA polymerase is important. The fidelity of the DNA polymerase in a PCR reaction determines the similarity between the sequence of the PCR product and the original template. *Taq* DNA polymerase sometimes incorporates an incorrect base in the growing DNA strand, and this error is propagated during subsequent rounds of cycling. The higher the fidelity, the more closely the sequence

of the PCR product reflects the sequence of the original DNA template. A range of DNA polymerases is commercially available, and certain enzymes have demonstrably higher fidelity. In addition to intrinsic differences among the various heat-stable polymerases, fidelity is influenced by a number of factors. It is therefore possible to increase or decrease the number of mismatches between the product and initial template. Conditions of low fidelity may be chosen to introduce random point mutations into a PCR product. More general applications benefit from accurate amplification. Fidelity is improved by keeping polymerase, dNTP, and  $MgCl_2$  concentrations as low as practical, using the same concentrations of each of the four dNTPs, maintaining an annealing temperature near the  $T_m$  of the primers, and programming a short extension segment and as few cycles as practical.

### Cross-Contamination

Because PCR primers are incorporated into each molecule of PCR product, amplicons are themselves suitable templates for amplification. Re-amplification of previously amplified DNA is a major problem for PCR. To reduce the likelihood of contamination of reagents, separate laboratory work areas should be designated for reagent preparation, sample preparation, reaction assembly and thermal cycling, and post-PCR analysis. Depending on the analytical rigor required and the resources available, well-isolated rooms for each step of the process will be beneficial. In the research laboratory, however, it is more common to rely on separate work areas and equipment for pre- and postamplification work and gowning of laboratory personnel in cleanroom garments. Laboratory equipment, especially pipettors and shared equipment, and laboratory personnel are the most common sources of PCR product contamination. Clinical laboratories or other analytical laboratories now employ physical separation of work areas and equipment in addition to a biochemical method using the enzyme uracil DNA glycosylase (UNG) to prevent amplicon contamination. If PCR reactions are performed with dUTP rather than dTTP, amplicons will be susceptible to digestion by UNG. This method has been called PCR sterilization. The need to avoid contamination with amplified DNA constitutes an incentive to use real-time PCR for qualitative as well as quantitative assays. With real-time PCR, tubes containing amplified DNA need never be opened. No matter what precautions are taken, negative controls containing no DNA template must always be included with each batch of PCR reactions. If low-copy detection is the assay goal, then multiple negative controls are required to adequately test for amplicon contamination.

## Reverse Transcription PCR

PCR can be used to detect and quantify RNA if RNA is first reverse-transcribed to complementary DNA (cDNA). Reverse transcriptases from Moloney murine leukemia virus (MMLV-RT) or avian myeloblastoma virus (AMV-RT) are commonly used. Either the buffer optimal for the reverse transcription (RT) or the PCR buffer is suitable in most cases, and reverse transcription is typically performed at 37–42°C for 15–60 min. Because these enzymes are heat-labile, they are inactivated during the first denaturation segment of PCR. Heat-stable reverse transcriptases enable reverse transcription at higher temperatures to denature RNA secondary structure. In the presence of  $Mn^{2+}$ , some DNA-dependent DNA polymerases such as the enzyme from *Thermus thermophilus* (*Tth* DNA polymerase) have activity on RNA templates. Using  $MnCl_2$  for reverse transcription can enable cDNA synthesis with the same enzyme used for PCR. Unless a balance between  $MnCl_2$  and  $MgCl_2$  is carefully identified,  $Mn^{2+}$  must be removed or chelated, and  $Mg^{2+}$  must be added prior to PCR. RT-PCR can be performed within intact cells (*in situ* PCR) to identify cells expressing particular genes or to assess the presence of disease-related genes. Thermal cyclers are available to automate the process on microscope slides.

## Applications

### Clinical Diagnostics

The main clinical application of PCR technology is in the diagnosis of disease, and in many cases the speed and simplicity of PCRs have revolutionized clinical diagnosis. Bacteria that are difficult or impossible to culture on artificial media can now be detected by PCR. The causative organism of syphilis, *Treponema pallidum*, can be detected by a PCR assay in which a gene encoding a specific membrane protein is amplified. PCR is being employed to investigate the pathogenicity of *Mycoplasma genitalium*. As few as four organisms can be detected by this method. PCR-based detection assays have also been developed for *Mycobacterium tuberculosis*, an organism that takes up to several weeks to identify by conventional means owing to its slow growth on artificial media. *M. tuberculosis*, the bacterium that causes tuberculosis, infects about one-third of the world's population and is most prevalent in developing countries. Recently, this organism has re-emerged as a significant pathogen in the developed world, especially among the poor and homeless, and antibiotic-resistant strains are developing. PCR tests have become essential for rapid diagnosis and epidemiology of diseases such as tuberculosis.

Amplification of viral genes forms the basis of PCR-based detection systems for viral pathogens. The human immunodeficiency virus (HIV), which is responsible for AIDS, is currently detected primarily by immunological means. However, as with most viral infections, it takes some time following infection for antibodies to develop, and there is therefore a period when a patient infected with the virus would appear negative by conventional tests. A PCR assay can be used to detect the presence of the virus in this case. Proviral DNA that has integrated into the genomes of leucocytes can be detected, or the viral RNA genome can be detected in plasma by RT-PCR. Identification of HIV by PCR methods has played an important role in AIDS diagnostics and research, as well as improved safety testing in blood banks. PCR assays have also been used in epidemiological studies and in the identification of other retroviruses such as human T-lymphotropic virus types 1 and 2 (HTLV-1 and HTLV-2). PCR procedures have also been developed to detect human papillomaviruses. This diverse group of viruses can cause a number of diseases. A PCR assay can distinguish the relatively harmless strains from those that cause serious diseases such as cervical cancer. Current laboratory methods for the diagnosis of human enteroviruses, which cause infection in children, are slow and lack sensitivity. Detection is hindered by the low level of viruses present in clinical specimens. PCR technology, however, provides a rapid and accurate diagnostic test. PCR assays have also been used to detect coronaviruses, cytomegalovirus, human herpesvirus type 6, adenovirus, Epstein-Barr virus, rotaviruses, human parvovirus, and herpes simplex viruses, among many others. In addition to detection, PCR assays can be designed to differentiate between different strains or serotypes of a particular virus.

Parasitic infections cause important human diseases such as leishmaniasis and malaria. About 40% of the world's population is at risk from malaria, and drug-resistant strains have emerged and are spreading rapidly. As well as being helpful in diagnosis of disease, a PCR assay can distinguish between drug-resistant and drug-sensitive strains, thus enabling effective treatment to be prescribed.

Many PCR diagnostic kits are now commercially available. Hoffman-La Roche has introduced kits for *Chlamydia*, *M. tuberculosis*, HIV, hepatitis C virus, and others. It is likely that an even wider range of PCR diagnostic kits will become available, and PCR testing will continue to have a huge impact in the clinical diagnostic laboratory. Despite the simplicity and rapidity of PCR from the perspective of the research laboratory, it is viewed as a complex test in the clinical laboratory. The expenses of highly

trained personnel and commercial PCR kits coupled with concerns about false positive test results due to contamination with previously amplified DNA have so far confined this promising technology to clinical research and specialty testing labs. Eventually, improved technology and assay automation will enable PCR testing to be as common in diagnostic laboratories as immunoassays.

### Molecular Genetics

In addition to being an invaluable tool for the detection and diagnosis of infectious diseases, PCR tests have also proved useful in the diagnosis and analysis of genetic diseases. Many genetic disorders are caused by specific mutations, and the fragment of DNA involved can be amplified by PCR. DNA sequencing, high-resolution size analysis on sequencing gels, single-strand conformation polymorphism analysis, Southern blotting and probe hybridization, allele-specific oligonucleotide probes, and other techniques are used to test for the presence of mutations. This approach has been used to detect mutations causing diseases such as sickle cell anemia, beta-thalassemia, cystic fibrosis, and many others. Genetic diseases caused by trinucleotide repeat expansion can be tested using PCR followed by high-resolution electrophoretic analysis on sequencing gels. A commercial test for fragile X syndrome employs novel PCR reagents and thermal cycling conditions to enable amplification of (CGG) repeats up to 800 repeat units in length in the same reaction containing a normal allele (usually 29–31 repeat units). In general, PCR should be considered a versatile template onto which can be superimposed known DNA sequences for any disorder, whether genetic or infectious in nature, to rapidly configure a high-performance test.

PCR is routinely used in the analysis of human leucocyte antigen (HLA) polymorphisms (HLA typing) to assess donor compatibility prior to bone marrow or organ transplantation. The use of PCR in transfusion medicine is also being investigated, and the basis of a system for ABO blood typing using PCR has been described.

### Prenatal Diagnostics

Prenatal diagnosis of genetic disease is normally carried out on a sample of amniotic fluid obtained by amniocentesis or by chorionic villus sampling (CVS). Conventional diagnostic tests for diseases such as cystic fibrosis can take as long as 2 weeks. Results of a PCR test can be available in 1 day. If the option to terminate a pregnancy is taken, this time savings can

be of enormous benefit. The availability of PCR technology creates an incentive for the development of noninvasive prenatal sampling techniques. Because amniocentesis and CVS carry a certain amount of risk, less invasive sampling procedures are desirable. A small number of cells of fetal origin circulate in the maternal blood. Methods to purify these cells have been described. Mutations and polymorphisms on the Y chromosome already can be tested using maternal blood samples without the need to purify fetal cells. It seems likely that in the future PCR tests will be used for prenatal diagnosis of a whole range of genetic diseases from a sample of maternal blood.

PCR testing is currently available for preimplantation genetic diagnosis for *in vitro* fertilization. One cell is removed from an eight-cell zygote for PCR testing.

### Basic Research

PCR has become an indispensable tool in the molecular biology laboratory. Many traditional methods and protocols have now been replaced by PCR-based techniques. One of the most common techniques employed by molecular biologists involves the cloning of DNA fragments into plasmid vectors. The plasmids are maintained in bacterial strains. To determine which bacterial colony contains the plasmid of interest, transformant colonies can be analyzed by PCR using primers designed from the vector (plasmid) DNA, bracketing the insert. In this way, colonies can be screened to find one containing a plasmid with an insert of a particular size, obviating the need to screen transformants by plasmid DNA preparation followed by restriction enzyme digestion. PCR can also be used to screen libraries for clones containing a particular DNA fragment or gene. This strategy dispenses with the filter hybridization step and can be both quicker and more sensitive than traditional methods. PCR is also invaluable in mutagenesis, radioactive, and nonradioactive labeling of DNA fragments, and many other applications. In addition, the technology developed for PCR amplification has been applied to the extremely important techniques of DNA sequencing and gene expression analysis.

PCR is being used in phylogenetic and evolutionary studies. PCR amplification and screening of ribosomal RNA (rRNA) genes and mitochondrial DNA have been used to estimate relationships between species and subspecies. Besides studies on the relationships of contemporary species, PCR allows studies on extinct species because it can be performed on material in museum collections. Amplification and sequencing of mitochondrial DNA are also used in evolutionary studies.

## Forensics

PCR has become an essential tool in forensic science. Many methods that exploit differences in DNA to identify individuals or to distinguish between individuals require large amounts of DNA (>100 ng). However, PCR permits the amplification of minute amounts of DNA from biological evidence found at the scene of a crime and has greatly facilitated the identification of individuals. Now, sufficient DNA for analysis can be obtained from very small amounts of biological material, such as a single hair or a small blood stain.

## Other Applications

Monitoring of foods for pathogens is increasingly performed using PCR analysis. Direct detection of microbial DNA or RNA can enable detection of contamination before visible signs appear. Assays for enterotoxigenic *E. coli* (*E. coli* 0157:H7), *Listeria monocytogenes*, *Salmonella*, and other pathogens are increasingly a component of food safety testing. Food products and ingredients can be tested for the presence of genetically modified organisms using PCR primers specific for the inserted gene sequence. Environmental samples can be tested for coliform and other bacteria or for biowarfare agents such as smallpox or anthrax. Because of its exquisite sensitivity, PCR amplification seems assured to find even more applications across research and analytical disciplines wherever there is a need to detect small amounts of genetic material.

## Natural Rubber

**A Krishen and M A Schafer**, The Goodyear Tire & Rubber Company, Akron, OH, USA

© 2005, Elsevier Ltd. All Rights Reserved.

## Introduction

During 2001, the world's natural rubber consumption was 7.07 million metric tons and 75% of it was

used in tires and related products. Natural rubber, which contains polyisoprene as the main constituent, is present in over 1000 plant species. However, the vast majority of the world's natural rubber production is derived from the tree *Hevea brasiliensis*. Written references to natural rubber date back to the late fifteenth century following the voyages of Columbus, although certain articles made of the rubber were used earlier in South America.

Serious investigations of rubber were first made in the mid-1700s by Charles de la Condamine and Francois Fresneau, who refer to it as caoutchouc,

an American Indian word meaning weeping wood. Joseph Priestley is credited for coining the word rubber when he noticed that gum from the *Hevea* tree could be used to rub out pencil marks.

Rubber is composed of particles ranging from 0.01 to 15  $\mu\text{m}$  in size in the cytoplasm or vacuolar sap of plant cells and occurs as a milky cytoplasmic suspension that exudes from a wound or an incision made in the plant. *Hevea* contains an articulated anatomizing laticifer system, which can be drained by tapping into the phloem layer of the trunk. The rubber content in *Hevea* latex is 30–40%. *Hevea* clones in current usage have been selected for high rubber production and the replenishment of rubber following controlled tapping make this plant the most important commercial source of rubber.

Structural characterization of naturally occurring polyisoprenes sheds some light on the biosynthesis mechanism of rubber formation, the origin of outstanding properties of natural rubber, and the role of rubber in rubber trees. Nuclear magnetic resonance (NMR) analysis, based on terpenes and polyprenols as models, disclosed the structure of both terminal groups of the rubber chain. Structural evidence indicated the biosynthesis of natural rubber starts from *trans*, *trans*-farnesyl diphosphate or *trans*, *trans*, *trans*-geranylgeranyl diphosphate and terminates by dephosphorylation to form a hydroxyl terminal group. The biosynthesis of natural rubber was presumed to start from unidentified initiating species containing two *trans*-isoprene units and a peptide group and to terminate forming a phospholipid terminal group. The initiating group of natural rubber associated with proteins formed branch points, which can be decomposed by enzymatic deproteinization. The branch points formed by a phospholipid group were decomposed by transesterification with sodium methoxide. Rapid crystallization of natural rubber was explained by the presence of mixed fatty acids synergistically with linked fatty acids, which were included in phospholipid. Saturated fatty acids linked to the rubber chain-induced crystallization, while mixed unsaturated fatty acids acted as plasticizer and accelerated the crystallization rate. This was confirmed by the preparation of model *cis*-polyisoprene grafted with stearic acid. The green strength of natural rubber decreased to the same level as synthetic *cis*-polyisoprenes after transesterification, indicating the effect of branching formed by the phospholipid terminal group and fatty acids in natural rubber. The role of natural rubber in *Hevea* trees was analyzed using natural rubber from *Hevea* trees never tapped before. The formation of hard gel and oxidative degradation during the storage of natural

rubber in *Hevea* trees suggested that natural rubber acted as a radical scavenger to remove hydroperoxide.

Commercial unmilled rubber is not completely soluble in any of the common solvents – benzene, chloroform, or petroleum. The insoluble portion, called gel, contains most of the nitrogenous impurities while the solution contains molecules of rubber representing a wide range of relative molecular masses. The amount of gel, defined as residue on a filtration screen, depends on the solvent used and decreases on prolonged immersion. Fresh latex from trees that are regularly tapped has an initial low-gel content, which increases rapidly on storage. The gel phase consists of internally cross-linked insoluble particles with an average diameter of 120 nm. When dry rubber is extracted with a solvent, the uncrosslinked rubber diffuses out leaving the insoluble rubber particles held together by the residual nonrubber network.

Ribbed smoked sheets (RSS) are made from intentionally coagulated latex. In this process, strained latex is diluted with water to ~15% solids, strained again to remove particulate matter, and then coagulated by addition of an acid. The coagulum is compressed into 2–3 mm thick sheets and dried for 4–7 days in large smoke houses.

Technically specified rubber is produced from intentionally coagulated and crumbled field latex, which is converted to a blanket and dried in an air circulating drying oven at 110–125°C.

In addition to rubber, latex contains 0.3–0.7% ash, 1–2% nitrogenous compounds, ~2% resins, and 1–2% sugars and related compounds. The proteins represent most of the nitrogenous compounds in the latex and upon hydrolysis yield alanine, aspartic acid, dihydroxyphenylalanine, glutamic acid, histidine, leucine, ornithine, hydroxyproline, tyrosine, and valine. Lecithin, glycerophosphoric acid, fatty acids (palmitic, stearic, arachidic, oleic, and linoleic), sterols, resin acids, wax, and quebrachitol are some of the other nonrubber constituents. The mineral constituents present in the ash consist of potassium, magnesium with traces of copper, iron, and manganese.

## Identification and Characterization

Manufacture of rubber products requires the incorporation of fillers such as carbon black, silica, and clay, pigments, sulfur, accelerators, retarders, resins, antioxidants, antiozonants, extending oils, zinc oxide, and a variety of other elastomers. The complexity and the variety of compounding ingredients normally present in articles containing natural rubber necessitate the use of a multitude of analytical techniques depending on the information required.

## Microstructure

Microstructure is defined as the order and orientation in which monomer units combine together to form the polymer backbone chain. In *Hevea* rubber, the orientation of the isoprene units in the polymeric chain consists of a dimethylallyl terminal unit, three *trans*-1,4-isoprene units, a long block of *cis*-1,4-isoprene units, and a *cis*-terminal isoprenyl unit.

In comparison, four different orientations for the isomer units can be derived by synthetic polymerization of isoprene: *cis*-1,4-, *trans*-1,4-, *trans*-3,4-, and *trans*-1,2- additions. The last two addition orientations produce asymmetric carbon atoms. An identical configuration of asymmetric carbon atoms is referred to as isotactic, regular alternating is syndiotactic, and random is atactic. Another consideration is the successive addition of monomer units in head-to-head, head-to-tail, or tail-to-tail configurations, though head-to-tail is preferred due to steric hindrances. The microstructure of *Hevea* rubber is predominantly *cis*-1,4- units, eliminating the tacticity concern. Because of its biochemical origin, the addition of isoprene units is almost entirely in a head-to-tail orientation.

## NMR Spectroscopy

NMR spectroscopy and Fourier transform infrared (FTIR) spectroscopy are the main techniques used to provide microstructure information that is especially important for differentiating *Hevea* rubber from other types of naturally occurring and synthetic polyisoprene. Both proton ( $^1\text{H}$ ) and carbon ( $^{13}\text{C}$ ) NMR spectroscopy are used to obtain spectra of natural rubber in solution, and are shown in Figure 1. In the  $^1\text{H}$  NMR spectrum, the olefinic proton gives rise to a peak  $\sim 5.0$  ppm, the methylene protons  $\sim 2.0$  ppm, and the methyl protons  $\sim 1.6$  ppm.

In the  $^{13}\text{C}$  NMR spectrum, the tetra-substituted olefinic carbon gives rise to the peaks from 130 to 140 ppm. The tri-substituted olefinic carbon accounts for the peaks from 118 to 128 ppm, and the aliphatic methyl carbon results in peaks from 20 to 25 ppm. This latter set of peaks can be used to distinguish *cis*-1,4-polyisoprene from *trans*-1,4- and 3,4-polyisoprenes. Either set of olefinic bands can differentiate *cis*-1,4- from 1,2-polyisoprene. Because of this,  $^{13}\text{C}$  NMR can readily be used for distinguishing other isomeric types of polyisoprene from *cis*-1,4-polyisoprenes, whether they are synthetic or natural in origin. Distinguishing a synthetic high *cis*-1,4-/low *trans*-1,4-polyisoprene from *Hevea* can present problems using  $^1\text{H}$  NMR. This problem can be overcome by using  $^{13}\text{C}$  NMR.

**Figure 1** Nuclear magnetic resonance spectra of natural rubber. (A) 300 MHz  $^1\text{H}$  NMR spectrum. Pulse delay 8.0 s; acquisition time 1.8 s; 32 transients co-added;  $50^\circ\text{C}$ ; 0.5% wt/vol in  $\text{CDCl}_3$ . (B) 75 MHz  $^{13}\text{C}$  NMR spectrum. Pulse delay 2.6 s; acquisition time 0.4 s; 2400 transients co-added; 5% wt/vol in  $\text{CDCl}_3$ ; ambient temperature. (Provided by courtesy of The Goodyear Tire & Rubber Company, Akron, OH.)

## FTIR Spectroscopy

Infrared spectroscopy is also used to provide microstructure information, though quantitative data must be obtained by comparison to standards of known composition. Typically, spectra are obtained from cast or pressed films of gum polymers. Carbon black and other fillers in compounded stock or vulcanizates can cause problems since they either absorb too much of the light energy or their characteristic spectra may be superimposed on the polymer spectra. Procedures using devulcanization, dissolution of lightly cross-linked fractions of the polymers, microtomed sections, and microdiamond anvil sampling cell with FTIR microscopy are commonly employed to overcome these problems. However, oxidation during some of these sampling procedures may affect the quantitative structural information.

**Figure 2** Infrared spectrum of natural rubber. Film cast from 1% wt/vol solution of rubber in carbon disulfide onto a KCl disk; 100 scans co-added; resolution  $2\text{ cm}^{-1}$ . (Provided by courtesy of The Goodyear Tire & Rubber Company, Akron, OH.)

An FTIR spectrum of natural rubber is shown in **Figure 2**. A number of peaks corresponding to unique molecular vibrations around the carbon-carbon double bond are observed. The CH stretch from 1,4-addition and the carbon-carbon double bond vibrational band are observed at  $3000$  and  $1665\text{ cm}^{-1}$ , respectively. In five other wavenumber regions,  $742$ ,  $764$ ,  $840$ ,  $1130$ , and  $1315\text{ cm}^{-1}$ , *cis*-1,4-polyisoprene has bands corresponding to vibrations of the  $-\text{C}(\text{CH}_3)=\text{CH}-$  group. In each case, *trans*-1,4-polyisoprene units have similar bands ranging from 3 to 20 wavenumbers higher, shifted toward shorter wavelengths. Resolution of the *cis* and *trans* bands is difficult, even with FTIR, in situations where low levels of *trans*-1,4-polyisoprene are blended with *Hevea*, or with synthetic 1,4-polyisoprenes containing a small amount of *trans*.

Infrared spectra of products obtained by heating the polymer in a test tube or in special heating equipment are also used to identify polymers in vulcanizates. The pyrolysis temperature is a critical parameter since the same polymer can give different spectra when pyrolyzed at different temperatures. Comparison of pyrolysis products obtained by heating carbon black containing vulcanized compounds can be used to distinguish *Hevea* from synthetic polyisoprene.

## Micromorphology

Performance of rubber compounds is affected by micromorphology, such as polymer compatibility and carbon black distribution. Transmission electron microscopy has been commonly used to examine micromorphology. More recently, atomic force microscopy, also referred to as scanning probe microscopy, has been used for this purpose. Tapping mode atomic force microscopy can be used to distinguish two different polymer domains in unfilled rubber

blends. Filler morphology was also examined in the filled natural rubber and filled rubber blend compounds. Silica and carbon black showed different behavior in the rubber blend. Carbon black lies predominantly in the polybutadiene rubber domain whereas silica exists in the natural rubber domain.

## Analysis of Nonrubber Constituents

Several nonrubber constituents such as  $\beta$ -sitosterol, fatty acids, and proteins, all naturally occurring in *Hevea*, are of importance in analysis. Natural rubber can be differentiated from a synthetic high *cis*-1,4-polyisoprene, as long as it exceeds 10% by weight in a mixture, through detection of  $\beta$ -sitosterol in the extract of either the rubber or vulcanized products. Typically,  $\beta$ -sitosterol is separated from other extracted components using thin-layer chromatography (TLC) followed by cupric acetate spray reagent for visualization. Gas chromatographic analysis of the silyl derivative can also be employed. Quantification of natural rubber based on the  $\beta$ -sitosterol content is not possible as  $\beta$ -sitosterol content is not consistent from batch to batch.

Fatty acids are determined after extraction using either gas chromatography (GC) or high-pressure liquid chromatography (HPLC). With either technique, the fatty acids can be measured either directly or after derivatization with methylating, silanizing, or ultraviolet (UV) chromophore-generating reagents. This approach can also be used to determine fatty and rosin acids added as compounding ingredients in cured samples.

The protein content of products intended for medical and health-related markets have been of special concern in recent years due to the observation of human allergic and anaphylactic reactions. Three colorimetric methods, modified Lowry, Bradford, and Pierce BCA reagent, are currently used to determine aqueous extractable proteins, though all three lack specificity to some degree. Electrophoresis, size-exclusion chromatography, amino acid analysis, and enzyme-linked immunosorbent assays (ELISAs) have been used to improve specificity, but are time consuming, expensive, and require an experienced analyst. The American Society for Testing and Materials (ASTM) has established two methods for determination of proteins, D5712 based on the modified Lowry colorimetric test and D6499 based on ELISA. Determination of the nitrogen content of *Hevea* can serve as another measure of its protein content, although this is not accepted by regulatory agencies. Standard test methods for nitrogen, ASTM D3533 and International Organization for Standardization (ISO 1656), use a factor to convert from nitrogen to protein.

**Figure 3** Thermogravimetric analysis of natural rubber (RSS): 6 mg heated in vacuum at  $10^{\circ}\text{C min}^{-1}$  to  $485^{\circ}\text{C}$ ; in nitrogen to  $570^{\circ}\text{C}$ , and in air at  $22^{\circ}\text{C min}^{-1}$  to  $990^{\circ}\text{C}$ . ## Quantitative Compositional Analysis

Thermogravimetric analysis (TGA) provides a rapid scanning technique to determine the ratio of the major components in raw or cured stocks. Using a 10–50 mg sample with appropriate heating parameters, four fractions are observed (Figure 3):

1. Volatile matter representing moisture, oils, plasticizers, polymer-diluents, curatives, antioxidants, antiozonants, and other components with boiling points below  $300^{\circ}\text{C}$ .
2. Polymeric components representing polymers, fibers, processing oils, and resins that degrade between  $300^{\circ}\text{C}$  and  $750^{\circ}\text{C}$ .
3. Oxidizable materials representing carbon black, graphite, and carbonaceous residues from some polymers.
4. Inorganic ash representing metallic oxides, fillers, zinc oxide, and residues from elastomers.

The first two fractions are produced either in a nitrogen atmosphere or under vacuum at 70 Pa (0.5 mm Hg). Accurate quantification requires appropriate corrections to allow for the overlap of the process oil and resins with the polymer decomposition region along with the serious complication observed for elastomers with a heteroatom in the monomer unit like acrylonitrile-butadiene, chloroprene rubber, chlorobutyl rubber, polyvinyl chloride (PVC), chlorosulfonated polyethylene, polyacrylates, fluoroelastomers, epichlorohydrin rubber, etc. Most of these polymers produce volatile components below  $300^{\circ}\text{C}$  and leave a carbonaceous residue after degradation, which oxidizes with the carbon black

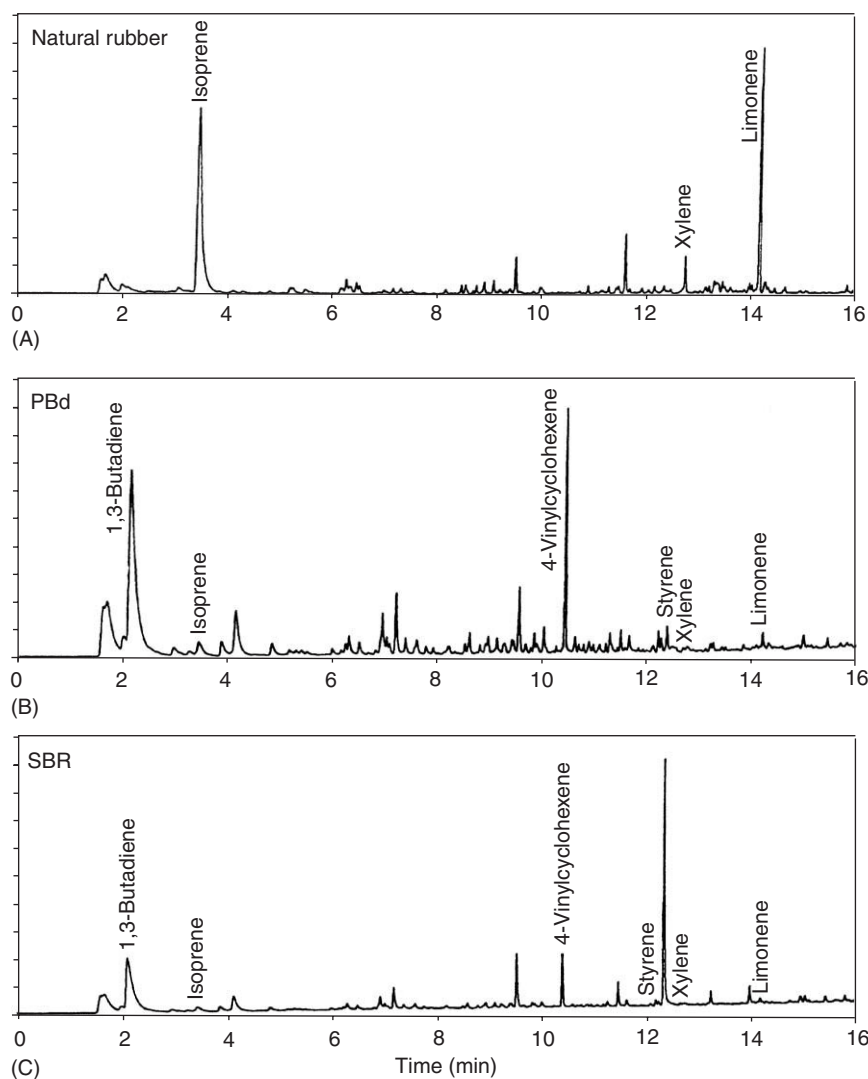

fraction. With the increasing use of short fibers to reinforce vulcanizates, their degradation also complicates interpretation and quantification.

Polymer ratio calculations based on the peak areas even for a mixture of polymers, which are well resolved, should be based on a calibration curve obtained from compounds of known composition. Modified heating programs and automated high-resolution instrumentation, which adjusts the heating rate when the start of a peak is sensed, are helpful in providing better discrimination in some cases.

Pyrolysis in an inert atmosphere under precisely controlled conditions (Figure 4) generates duplicable amounts of products, which are separated by capillary GC and provide an estimate of the ratio of polymeric constituents. Natural rubber produces isoprene and limonene as two of the characteristic products, which distinguish it from polybutadiene (BR), styrene-butadiene co-polymer (SBR), butyl rubber (IIR), and some of the other polymers. Quantification involving a mixture of polymers requires calibration curves derived from similar combinations of polymers (Figure 5). Cured and uncured formulations require separate calibrations and the differences in the microstructure of a polymer affect the products obtained on pyrolysis.

## Analysis for Additives in Vulcanized Rubber

As previously described, TGA can provide a wealth of information about the composition of rubber

**Figure 4** Pyrolysis/capillary gas chromatograms of (A) natural rubber, (B) BR, and (C) SBR; 80  $\mu\text{g}$  pyrolyzed at 770°C for 10 s and chromatographed on 30 m  $\times$  0.32 mm DB-1701 (J & W Scientific Company) capillary column temperature programmed from  $-20$  to 250°C at 10°C min $^{-1}$ . samples. Additional analyses of a cured product are occasionally required in cases addressing product integrity or to detect errors in compounding.

### Extraction

The first step involves sample preparation and extraction of additives. Preparation of samples for chemical analysis is listed in ASTM D3183 and ISO 4661/1.2. Acetone and methanol are common solvents used for Soxhlet extraction following procedures such as ASTM D297 and ISO 1407. Soxhlet extractions can often require up to 16 h for completion. Thus, rapid solvent extraction techniques using ultrasonic baths or homogenizers, microwave heating, or pressurized extractions such as supercritical fluids are finding ever-increasing use. Extractions solely utilizing heat have also been reported. The extract can contain

rubber additives such as antioxidants, antiozonants, accelerators (uncured samples), or accelerator fragments (cured), resins, fatty and rosin acids, and oils.

### Antioxidants and Antiozonants

Antioxidant and antiozonant types most commonly used are aromatic amines or phenolics, though others are also employed, and can be determined using a variety of techniques such as UV-visible spectrophotometry, FTIR, near-infrared spectroscopy, TLC, GC (if the material can be volatilized), supercritical fluid chromatography, and HPLC. Identification of unknown antioxidants requires a separation technique like chromatography followed by mass spectrometry, NMR, FTIR, X-ray crystallography, etc. Standardized TLC methods are given in ASTM D3156 and

**Figure 5** Pyrolysis/capillary gas chromatograms of natural rubber/SBR blends. (Provided by courtesy of The Goodyear Tire & Rubber Company, Akron, OH.)

ISO 4645/2, whereas a standardized HPLC method is listed in ISO 11089.

### Accelerators

As the name implies, accelerators are used to increase the rate of sulfur vulcanization reaction in polymers containing unsaturated backbones. Many accelerators contain sulfur that chemically reacts during vulcanization, resulting in decomposition of the original accelerator. Accelerator types such as sulfenamides, thiurams, and mercaptobenzothiazyl disulfide (MBTS) are typically not detectable as the intact component in cured rubber articles, but can usually be measured unchanged in the raw compounded stock. Upon vulcanization, mercaptobenzothiazole (MBT) is produced from MBTS and sulfenamides, the latter also giving an amine, while thiurams react to produce the corresponding dithiocarbamates, or in some cases carbon disulfide and the corresponding amine. Guanidine and dithiocarbamate type accelerators can be detected as the intact component, though the corresponding aromatic amine and secondary aliphatic amine, respectively, are also produced in lesser quantities. Occasionally, more than one accelerator is used in compounds and this may lead to difficulties in identification of the exact combination of accelerators added.

Unlike vulcanized samples, uncured compounds must be extracted with a cold solvent to prevent

onset of the vulcanization reaction. Methanol and isopropanol are the preferred extraction solvents for uncured compounds, which might contain thiurams since they can decompose even upon extraction with acetone. Techniques that have been employed for detection of accelerators from vulcanized samples include colorimetry, TLC, GC, and HPLC. GC is primarily used to determine MBT and amine fragments, whereas HPLC is useful for determining guanidines and MBT. The same techniques, as well as FTIR, have proven useful for analysis of uncured compounds. Here, HPLC is advantageous for the determination of sulfenamide, MBTS, and guanidine accelerators. ISO 11389 outlines the determination of accelerators using GC and TLC.

N-nitrosamines generated at low levels from secondary amines liberated from some of the accelerators can cause health concerns and have been subject to regulation. Volatile N-nitrosamines are quantified using GC with a thermal energy analyzer.

### Sulfur Cross-linking

Although relative amounts of crosslinking are estimated by physical properties, a rough estimate of the degree of curing is obtained by quantitating free sulfur (ISO 7269), extractable low relative mass polymeric species, or by determining the curing isotherm using differential scanning calorimetry.

The type and distribution of sulfidic links – mono, di, or poly – affects the properties of the vulcanized rubber and these are determined by scission with specific chemical reagents followed by determining the degree of swelling in a suitable solvent. NMR methods have also been developed to determine cross-linking.

### Extending Oils

Hydrocarbon oils are used as plasticizers or extenders in unsaturated polymers like *Hevea*. Oils often represent a significant amount of the rubber compound, up to 40 phr (parts per hundred of rubber) in natural/synthetic blends, but at lower levels when natural rubber is the only polymer. Oils are grouped into three types, paraffinic, naphthenic, and aromatic, but each type varies only in the proportions of these three different types. Paraffinic and naphthenic oils are most commonly used in compounds containing natural rubber. TLC provides a convenient means of identifying oil type by visualizing the separated spots under short (254 nm) and long (366 nm) wavelength UV lamps.

Aromatic oils have the lowest mobility and fluoresce at the long wavelength, while at the short wavelength produce a dark spot. Naphthenic oils have an intermediate mobility and are only observed as a dark spot under the short wavelength light, whereas paraffinic oils have the highest mobility but can only be observed as fleeting spots as the TLC solvent dries. GC, HPLC, and size-exclusion chromatography with photodiode-array and differential refractive index detectors have been applied to extender oil determination. Infrared spectroscopy can also be used to identify and quantify oil type based on absorption at multiple bands.

### Metals

The determination of several metals is important to assuring proper compounding and minimal metal contamination known to be detrimental to vulcanization. Procedures for ashing samples are given in ASTM D297 and ISO 247. Manganese, known to inhibit rubber curing, is determined by photometric methods, ASTM D1278 and ISO 7780. Zinc, added as zinc oxide

to the compound, is determined using a titrimetric method involving chelation with ethylenediaminetetraacetic acid as in ASTM D297 and ISO 2454. Methods using atomic absorption spectrometry (AAS) have also been standardized for manganese and zinc as ASTM D4004 and ISO 6101. Other metals such as silicon, iron, and copper are also quantified using AAS.

Energy dispersive (ED) and wavelength dispersive (WDX) X-ray fluorescence analysis are both capable of identifying a large variety of elements. Quantification can suffer from matrix effects and from the fact that these are near-surface techniques. The quantity of residual ash generated during TGA is sufficient for identification of metals using a scanning electron microscope equipped with EDS.

### Introduction

A polymer is a substance composed of macromolecules, i.e., molecules built of a large number of small

molecules linked together by covalent bonds. Man-made polymers (synthetic polymers) are relatively new materials that did not exist until about hundred years ago. The first synthetic polymer, phenol-formaldehyde resin (Bakelite), appeared shortly before World War I. Nowadays, synthetic polymers are used in a variety of applications covering almost all areas

of human life. They can replace conventional materials with properties that are better in many aspects when compared to classical materials. Low density, possibility to adjust properties to required applications, resistance to moisture and chemicals, and easy workability are the main advantages of synthetic polymers.

Synthetic polymers can be classified as thermoplasts, which soften under heat and can be reversibly melted, and thermosets, which by the action of heat or chemical substance undergo chemical reaction and form insoluble materials that cannot be melted. Mixtures of molecules of relatively low molar mass (hundreds to thousands) that are able to react mutually or with other compounds and form cross-linked materials are often called synthetic resins. That is, synthetic resins such as epoxy or polyester or phenol-formaldehyde resins are thermosets. The term oligomer refers to a polymer molecule with relatively low molar mass (roughly below  $10\,000\text{ g mol}^{-1}$ ) whose properties vary significantly with the removal of one or a few of the units.

## Structure of Synthetic Polymers

The part of a macromolecule from which the macromolecule is built is called monomer unit, while the smallest part of a macromolecule that repeats periodically is called structural repeating unit. Polymers can consist of one or more kinds of monomer unit. The former are called homopolymers and the latter copolymers. Synthetic polymers are usually varied mixtures of molecules of different molar mass ( $M$ ) and possibly chemical composition and/or molecular architecture; that is, they are nonuniform

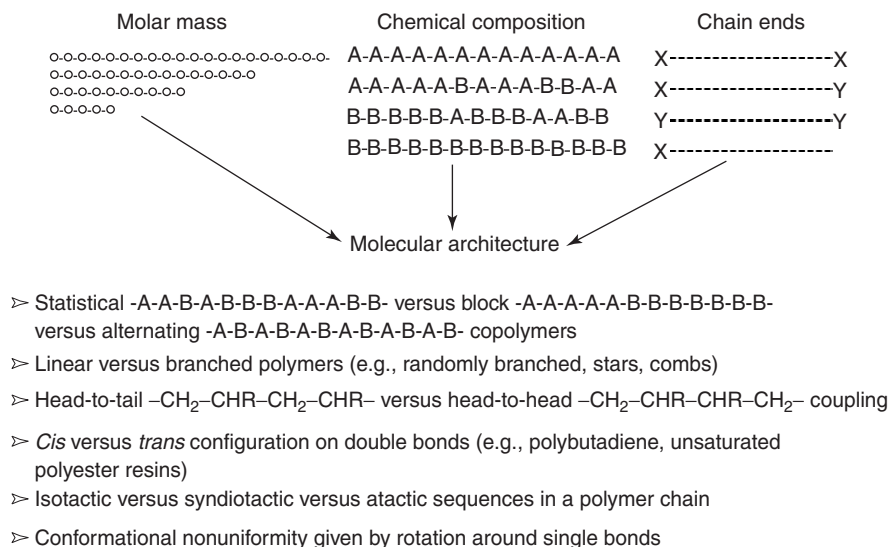

(polydisperse) materials. Examples of various non-uniformities are outlined in **Figure 1**. Polymers can be nonuniform in one or more properties. It is worth mentioning that monodisperse polymers (i.e., uniform with respect to all properties) are exceptional in the area of synthetic polymers.

It is essential for the polymer chemist and analyst to be aware of all possible nonuniformities of polymers in order to interpret the experimental data and understand the properties and behavior of polymers. Two polymer samples may be identical in one or more properties but may differ in others. Although the polymer properties are generally distributed, analysis can provide solely average values. Two polymer samples can be identical in an average property but the property distributions can be different. However, average properties are often used instead of distributions in order to simplify the description of a polymer sample or because the distribution cannot be determined due to the time or instrumental limitations.

In addition to molecular nonuniformity, many commercially important polymer-based materials are polymer blends, i.e., mixtures of two or more polymeric components.

## Molar Mass Distribution

Several notations are used in polymer science to express molar mass, namely molar mass or molecular mass (mass of polymer divided by the amount of polymer, dimension  $\text{g mol}^{-1}$ ), and relative molecular mass or molecular weight (mass of the polymer relative to 1/12 of the mass of the  $^{12}\text{C}$  atom, dimensionless). The number of monomeric units in

**Figure 1** Schematic description of possible nonuniformities in synthetic polymers.

**Figure 2** Differential molar mass distribution curve of polydisperse polystyrene. Averages by SEC-MALS:  $M_n = 100\,000\text{ g mol}^{-1}$ ;  $M_w = 334\,000\text{ g mol}^{-1}$ ;  $M_z = 704\,000\text{ g mol}^{-1}$ ;  $M_v$  (by viscometry) =  $307\,000\text{ g mol}^{-1}$ . Zimm plot for this sample is shown in **Figure 4**.

**Figure 3** Cumulative distribution curve corresponding to the differential distribution shown in **Figure 2**.

a macromolecule or oligomer molecule is called degree of polymerization ( $P$ ).

In contrast to low molar mass compounds a polymer does not have a single molar mass and almost all synthetic polymers are polydisperse in molar mass. Frequencies of particular molar masses in a given polymer sample are described by the molar mass distribution (MMD). The differential  $f(M)$  and cumulative  $I(M)$  MMD curves are used for the description of MMD. An example of the differential distribution curve is shown in **Figure 2**. Note: It is usual practice to express the molar mass axis in logarithmic scale. The area  $f(M) dM$  in the graph represents the weight fraction  $w$  of material having the molar mass between  $M$  and  $M + dM$ . According to the graph in **Figure 2**, the value  $f(M)$  of  $\sim 0.84$  corresponds to the molar mass of  $300\,000\text{ g mol}^{-1}$ . Taking a molar mass of  $310\,000\text{ g mol}^{-1}$  as  $M + dM$  the differential  $d(\log M) = 0.014$ . Then,  $0.84 \times 0.014 = 0.012$  is the weight fraction of a polymer having the molar mass in the range of  $300\,000\text{--}310\,000\text{ g mol}^{-1}$ . Additional information obtainable from **Figure 2** is the entire molar mass range ( $\sim 1000\text{--}3\,000\,000\text{ g mol}^{-1}$ ) and the molar mass of the most abundant fractions ( $\sim 200\,000\text{ g mol}^{-1}$ ).

Another way of graphical representation of MMD is the cumulative MMD as shown in **Figure 3**. The cumulative MMD is defined as:

$$I(M) = \int_0^M f(M) dM \quad [1]$$

The cumulative MMD allows easy determination of the weight fraction of a polymer below or above a particular molar mass or the weight fraction of polymer in a specific molar mass range. Using the curve in **Figure 3**, one can easily see that  $\sim 23\%$  molecules have

molar mass below  $100\,000\text{ g mol}^{-1}$  (77% above this limit) or 95% molecules have molar mass above  $1\,000\,000\text{ g mol}^{-1}$  or 72% molecules have molar mass in the range of  $100\,000\text{--}1\,000\,000\text{ g mol}^{-1}$ .

Graphical overlay of distribution curves can serve for comparison of a set of samples and finding even subtle differences among them. Note: Instead using the weight fraction it is possible to use the mole fraction. The frequency functions are then called the number distribution functions and subscripts 'w' and 'n' can be used in order to differentiate between the weight distribution and number distribution, respectively.

The important properties of the MMD curve are the number of peaks and whether a peak is symmetrical or skewed. They can provide information about the polymer composition or polymerization process. Two or more peaks indicate a blend of two or more polymers with different MMDs. Or it may indicate the presence of a single polymer prepared under more than one set of polymerization conditions (temperature, concentration of monomers, or initiator). Shoulders at the high molar mass or low molar mass regions of the MMD are signs of appreciable amounts of species with very high or low molar masses. It is important to note that these species can significantly affect the properties of the polymer. A high molar mass tail on the distribution curve often indicates the presence of branched molecules.

Several average molar masses are used in polymer practice. Different instrumental techniques provide different kinds of averages. They are defined as follows:

Number average:

$$\begin{aligned} M_n &= \int_0^\infty M f_n(M) dM = \sum_i x_i M_i \\ &= \frac{\sum_i n_i M_i}{\sum_i n_i} = \frac{\sum_i m_i}{\sum_i m_i / M_i} = \frac{1}{\sum_i w_i / M_i} \end{aligned} \quad [2]$$

Weight average:

$$M_w = \int_0^\infty M f_w(M) dM = \sum_i w_i M_i$$

$$= \frac{\sum_i m_i M_i}{\sum_i m_i} = \frac{\sum_i n_i M_i^2}{\sum_i n_i M_i} \quad [3]$$

Z-average:

$$M_z = \frac{\int_0^\infty M^2 f_w(M) dM}{\int_0^\infty M f_w(M) dM} = \frac{\sum_i m_i M_i^3}{\sum_i m_i M_i} = \frac{\sum_i n_i M_i^4}{\sum_i n_i M_i^2} \quad [4]$$

Viscosity average:

$$M_v = \left[ \int_0^\infty M^a f_w(M) dM \right]^{1/a} = \left[ \sum_i w_i M_i^a \right]^{1/a} \quad [5]$$

In the above equations,  $n_i$  is the number of moles,  $m_i$  is the mass,  $x_i$  is the mole fraction, and  $w_i$  is the weight fraction of molecules with molar mass  $M_i$ . The exponent  $a$  is the exponent of the Mark-Houwink equation. In thermodynamically good solvents, the values of  $a$  mostly range from  $\sim 0.7$  to  $0.8$ . If the exponent  $a$  becomes 1, the viscosity average becomes identical to the weight average. The  $M_v$  value lies between  $M_n$  and  $M_w$ , closer to  $M_w$ .

The different averages are differently sensitive to different molar masses. Namely,  $M_n$  is sensitive mainly to the fractions with low molar masses while  $M_w$  and particularly  $M_z$  are sensitive to high molar mass fractions. For monodisperse polymers, all molar mass averages are identical. The order of molar mass averages for polydisperse polymers is  $M_n < M_v < M_w < M_z$ . The ratio of  $M_w/M_n$  is a measure of the broadness of the MMD and is often called polydispersity or polydispersity index. The ratio  $M_z/M_w$  can be used as an additional parameter or can be alternatively applied instead of  $M_w/M_n$  if the  $M_n$  value cannot be reliably determined.

Molar mass averages and polydispersity can be calculated theoretically for various polymerization reactions. In the case of polycondensation of monomer type a-R-b (e.g., hydroxy acid) or the equimolar mixture of monomers a-R<sub>1</sub>-a and b-R<sub>2</sub>-b the average polymerization degrees are as follow:

$$P_n = \frac{1}{1-q} \quad [6]$$

$$P_w = \frac{1+q}{1-q} \quad [7]$$

$$P_w/P_n = 1+q \quad [8]$$

where  $q$  is the conversion. In the case of polycondensation of monomers with average functionality larger than 2, the average polymerization degrees

are:

$$P_n = \frac{1}{1-(qf/2)} \quad [9]$$

$$P_w = \frac{1+q}{1-q(f-1)} \quad [10]$$

where  $f$  is an average monomer functionality (e.g., equimolar mixture of adipic acid and glycerol has  $f=2.5$ ).

The polydispersities of polymers prepared by free radical polymerization are 2 or 1.5 for the termination by disproportionation or combination, respectively. These values apply to products formed during a short time period when the concentrations of monomer and initiator are constant. In the course of free radical polymerization the monomer and initiator concentrations usually vary with conversion and consequently the polydispersity of the final product is broader.

The discrepancy between the experimental and theoretical values of molar mass averages and polydispersity can reveal side reactions. For instance, branching, which can arise as a result of chain transfer to polymer or due to the presence of polyfunctional impurities, markedly increases polydispersity.

Many important polymer properties depend on molar mass, e.g., melt and solution viscosity, tensile strength, toughness, impact strength, adhesive strength, elasticity, brittleness, abrasion resistance, flex life, softening temperature, solubility, chemical resistance, cure time, diffusion coefficient, film and fiber forming ability, ability to be fabricated, and processing temperature. Different molar mass averages can influence different polymer properties since either high molar mass or low molar mass species can primarily influence specific properties. The tensile strength is particularly related to  $M_w$  since it is most influenced by the large molecules in the material. The flex life is related to  $M_z$  because extremely large molecules are most important for this property. The glass transition temperature of oligomers increases with increasing  $M_n$  since the decreasing number of chain ends decreases the chain mobility and free volume. There is an empirical relationship of polymer melt viscosity having a 3.4 power dependency on  $M_w$ . Polymer rheology is strongly related to  $M_z$  reflecting the high molar mass tail of MMD.

It is important to note that there are no commonly good molar mass averages or MMD for a polymer sample. The optimum values depend on the nature of polymer and especially on the required end-use properties. A polymer sample known as good can serve as a reference to which other samples are compared.

## Analysis and Characterization of Synthetic Polymers

There are numerous techniques employed for the analysis and characterization of synthetic polymers. A number of them are used in other types of chemistry (e.g., nuclear magnetic resonance, infrared spectroscopy, liquid chromatography, gas chromatography, mass spectrometry) while some are applied mostly in the area of polymers (e.g., osmometry, light scattering, size-exclusion chromatography (SEC), field flow fractionation (FFF)). The focus of this article is in the methods used for the determination of average molar mass and MMD, because molar mass is a fundamental difference between the polymers and other organic compounds. In addition, it is essentially related to polymer properties and bears information about polymerization process and polymer degradation.

## Methods for the Determination of Molar Mass and Molar Mass Distribution

Molar mass of polymers can be determined by various methods (as summarized in Table 1). The following provides principal equations and points out advantages and limitations of particular methods.

### Method of End Groups

The results obtained by the method of end groups may be influenced by the presence of chain defects (overestimation of  $M_n$ ) or branching (underestimation of  $M_n$ ). The method is applicable solely to polymers with easily determinable end groups.

### Osmometry

Vapor pressure osmometry (VPO) calculates  $M_n$  using the equation:

$$\frac{\Delta T}{c} = B \left( \frac{1}{M_n} + A_2 c + \dots \right) \quad [11]$$

where  $\Delta T$  is the temperature difference of the solution and solvent,  $B$  is a calibration constant of the instrument obtained by measuring a compound of known molar mass,  $c$  is the concentration, and  $A_2$  is the second virial coefficient. The measurements are made at multiple concentrations and  $M_n$  is obtained by the extrapolation to zero. Serious disadvantage of VPO is excessive sensitivity to the presence of low molar mass compounds, such as residual monomers, solvents, or moisture, which can result in serious underestimation of  $M_n$ .

Membrane osmometry (MO) is another absolute method for the determination of  $M_n$ . The osmotic pressure  $\pi$  is related to the molar mass by the equation:

$$\frac{\pi}{c} = RT \left( \frac{1}{M_n} + A_2 c + \dots \right) \quad [12]$$

The extrapolation of the concentration dependency to zero provides  $M_n$ . If the sample contains oligomeric species that can permeate through the membrane the osmotic pressure is too low and the obtained  $M_n$  is overestimated. Consequently, polydisperse polymers with low molar mass tails are not suitable for the method. The advantage of VPO and MO is independency of chemical nonuniformity.

The second virial coefficient is an additional result that provides information about the polymer-solvent interactions and thus about thermodynamic quality of solvent that increases with increasing value of  $A_2$ . The  $A_2$  decreases with increasing molar mass, which explains decreasing solubility of polymers with increasing molar mass.

### Viscometry

Viscometric measurements are performed using a capillary viscometer (Ubbelohde, Ostwald). The measured quantity is the specific viscosity ( $\eta_{sp}$ ):

$$\eta_{sp} = \frac{\eta - \eta_0}{\eta_0} = \frac{t - t_0}{t_0} \quad [13]$$

where  $\eta$  and  $\eta_0$  are the viscosities of dilute polymer solution and pure solvent, respectively. In practice, the measurement of viscosity is replaced with the measurement of time ( $t$ ) needed for the solvent or solution to flow from one mark to the other. The concentration dependence of the specific viscosity can be described by Huggins equation:

$$\frac{\eta_{sp}}{c} = [\eta] + k_H [\eta]^2 c + \dots \quad [14]$$

where  $c$  is the concentration,  $k_H$  is the Huggins coefficient for given polymer, solvent, and temperature, and  $[\eta]$  is the intrinsic viscosity that is determined from the concentration dependency of the specific viscosity. The relation between the intrinsic viscosity and molar mass is given by the Mark-Houwink equation:

$$[\eta] = KM_v^a \quad [15]$$

where  $K$  and  $a$  are the constants for given polymer, solvent, and temperature. For many polymers these values can be found in the literature. The experimental determination of  $K$  and  $a$  requires a series of

**Table 1** Methods for the determination of molar mass of polymers

Method	Principle	Average type/range ( $\text{g mol}^{-1}$ )
Method of end groups	Determination of the concentration of the end groups by titration or spectral methods	$M_n$ Hundreds to 20 000
Vapor pressure osmometry (vapor phase osmometry)	Measurement of the temperature difference between droplets of polymer solution and pure solvent maintained in an atmosphere of solvent. Lower vapor pressure of solution compared to pure solvent results in the condensation of vapor into solution and temperature rise due to the released heat. Increase of vapor pressure due to the increased temperature compensates decrease of vapor pressure due to the presence of dissolved polymer	$M_n$ Hundreds to 20 000
Membrane osmometry	Measurement of osmotic pressure created by the flow of solvent into polymer solution through semipermeable membrane	$M_n$ 5000–1 000 000
Viscometry	Determination of the increase of viscosity of dilute polymer solution resulting from the presence of polymer molecules	$M_v$ Thousands to millions
Light scattering	Measurement of the intensity of light scattered by dilute polymer solution. The intensity is measured as a function of concentration and angle of observation	$M_w$ Hundreds to tens of millions
Ultracentrifugation		
(a) Sedimentation velocity	(a) Moving boundary is formed on application of a strong centrifugal field. The rate of boundary movement is measured	Various averages Thousands to tens of millions
(b) Sedimentation equilibrium Note: the method is rarely used for synthetic polymers	(b) The experiment is performed at lower rotation speed and measures the equilibrium concentration distribution of macromolecules that eventually form when sedimentation is balanced by diffusion	
Size-exclusion chromatography (gel permeation chromatography)	Separation of molecules according to their hydrodynamic volume during the flow through the column packed with porous packing. Determination of molar mass from the elution volume after column calibration, i.e., establishing the relation between molar mass and elution volume	Various averages and MMD Hundreds to millions
Matrix assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry	High molar mass ions are generated by irradiating a solid mixture of a polymer dissolved in a matrix compound with a pulsed laser beam. The matrix molecules absorb most of the laser's energy and thus the ionization process is 'soft' and produces molecular ions that are introduced into the mass spectrometer and analyzed. MALDI mass spectra are most often acquired using the time-of-flight technique that uses the differences in transit time through a drift region to separate ions of different masses	Various averages and MMD Hundreds to tens of thousands

samples with narrow MMD and known values of the intrinsic viscosity and molar mass. However, in practice the requirement of narrow MMD can be rarely fulfilled. The influence of polydispersity is relatively small when  $[\eta]$  is correlated with  $M_w$ . The constants can be considered as trustworthy for  $M_w/M_n < 1.5$ , correlation  $[\eta]$  versus  $M_w$  and molar mass range covering at least two orders of magnitude. The recommendations for reliable results are  $\eta_{sp}$  in the range of 0.2–0.8 and  $t_0 \sim 100$  s. An important feature of the intrinsic viscosity is that it increases with increasing temperature due to the expansion of polymer molecules.

### Light Scattering

Scattering of light is a natural phenomenon arising from the interaction of light with the matter. There are several equations describing the concentration and angular dependence of the intensity of light scattered by a dilute polymer solution. One of them is called the Zimm equation:

$$\frac{K^*c}{R_\theta} = \frac{1}{MP(\theta)} + 2A_2c + \dots \quad [16]$$

where  $c$  is the concentration of polymer in solution ( $\text{g ml}^{-1}$ ), for polydisperse polymer  $M$  is  $M_w$ ,  $A_2$  is

the second virial coefficient,  $K^*$  is an optical constant that for vertically polarized light is defined as:

$$K^* = \frac{4\pi^2 n_0^2}{\lambda_0^4 N_A} \left( \frac{dn}{dc} \right)^2 \quad [17]$$

where  $n_0$  is the refractive index of the solvent at the incident radiation wavelength,  $\lambda_0$  is the incident radiation wavelength at vacuum,  $N_A$  is the Avogadro number,  $dn/dc$  is the specific refractive index increment,  $R_\theta$  is the excess Rayleigh ratio defined as:

$$R_\theta = f \frac{(I_\theta - I_{\theta,\text{solvent}})}{I_0} \quad [18]$$

where  $I_\theta$  is the scattered light intensity of the polymer solution,  $I_{\theta,\text{solvent}}$  is the scattered light intensity of the solvent,  $I_0$  is the intensity of the incident radiation,  $f$  is an instrumental constant related to the geometry of the apparatus. The subscript  $\theta$  is the angle between the scattering direction and the incident light beam. In practice, the constant  $f$  is determined experimentally using a compound of well-known Rayleigh ratio (e.g., toluene).

$P(\theta)$  is the particle scattering function (the ratio of the intensity of radiation scattered at an angle of observation  $\theta$  to the intensity of radiation scattered at an angle zero,  $R_\theta/R_0$ ) that describes the decrease of the scattered light intensity with increasing angle of observation:

$$P(\theta) = 1 - \frac{16\pi^2}{3\lambda^2} R^2 \sin^2\left(\frac{\theta}{2}\right) + \dots \quad [19]$$

where  $\lambda$  is the wavelength of the incident light in a given solvent,  $R^2$  is the mean square radius (z-average in the case of a polydisperse polymer). The root mean square (RMS) radius ( $R$ , also called radius of gyration) describes the distribution of mass around the center of gravity and thus expresses the size of a particle regardless of its shape. It can be determined from the initial slope of the angular variation of the scattered light intensity. It is worth mentioning that the angular variation of scattered light intensity is negligible in the case of small polymers having  $R$  below  $\sim 10$  nm ( $M$  roughly  $100\,000 \text{ g mol}^{-1}$ ).

Light scattering experiments can be carried out either in batch mode using the light scattering photometer as a standalone instrument or in continuous flow mode when the light scattering instrument is used as a detector in SEC or FFF. In the batch mode, the sample is measured at several concentrations and the obtained data are processed using a Zimm plot, which allows simultaneous extrapolation to zero angle and zero concentration and thus the

**Figure 4** Zimm plot obtained by the measurement of five different concentrations ( $c1 = 3.28 \times 10^{-4} \text{ g ml}^{-1}$ ,  $c5 = 5.28 \times 10^{-5} \text{ g ml}^{-1}$ ) of polydisperse polystyrene. The intensity of light measured at 15 angles ( $23^\circ$ – $147^\circ$ ). Line 1 is the angular variation of the scattered light intensity at zero concentration; line 2 is the concentration dependence at zero angle. The slopes of lines 1 and 2 are used to compute  $R_z$  and  $A_2$ , respectively. The intersection of lines 1 and 2 is the reciprocal  $M_w$ . The factor 2896 was chosen automatically by software to spread the data points in the plot.  $M_w = 337\,000 \text{ g mol}^{-1}$ ;  $R_z = 34 \text{ nm}$ ;  $A_2 = 4.1 \times 10^{-4} \text{ mol ml g}^{-2}$ .

determination of  $M_w$ ,  $R_z$ , and  $A_2$ . An example of a Zimm plot is presented in Figure 4.

### Size-Exclusion Chromatography

SEC is the most important and widely used method for the determination of MMD. The most serious limitation of SEC is that it is a relative method requiring careful calibration of SEC columns, i.e., establishing the relation between molar mass and elution volume for the analyzed polymer. However, it has become a usual practice to calibrate the columns by polystyrene standards and to employ the polystyrene calibration to other polymers as well. This approach provides the polystyrene equivalent molar mass values, i.e., molar masses of polystyrene molecules of the same hydrodynamic volume as that of the analyzed polymer. It must be emphasized that the polystyrene equivalent molar masses can be up to a 100% or even more below or above the true values.

Application of a molar mass sensitive detector eliminates the column calibration. In principle, there are two kinds of the molar mass sensitive detectors. They are the light scattering photometers and viscometers. Actually the viscometers are not truly molar mass detectors since the measured quantity is the intrinsic viscosity and not the molar mass. The molar mass is determined from the experimental intrinsic viscosity and the so-called universal calibration, i.e., the relation  $\log(M[\eta])$  versus elution volume that is independent of polymer composition and structure. Likewise, in conventional SEC the obtained results are affected by the flow rate and temperature

fluctuations, injected mass, injected volume, column performance, and non-size exclusion separation mechanisms.

Low-angle light scattering (LALS) and multiangle light scattering (MALS) detectors differ in the number of angles at which the intensity of light is measured. A LALS detector operates at a single angle low enough (e.g.,  $7^\circ$ ) that can be considered zero. The disadvantage of a LALS detector is a strong tendency to signal noise caused by particles (dust, column shedding) in the mobile phase. This is given by the fact that large particles scatter light with the highest intensity at very low angles. In the case of a MALS detector, the intensity of light is measured at multiple angles simultaneously and then extrapolated to zero angle, which avoids the measurements at very low angles and reduces signal noise. In SEC-MALS the data for each elution volume slice are extrapolated to zero angle and molar mass and RMS radius are obtained from the intercept and slope of the plot, respectively (Figure 5). A refractive index detector determines the concentrations at particular elution volume slices. Because of very low concentrations in SEC columns the term  $2A_2c \ll 1$  and thus the concentration dependence can be neglected.

### Field-Flow Fractionation

FFF is an alternative separation technique to SEC that crosses the borders from soluble region into particle region. The separation takes place in a thin channel between two parallel plates where the sample flows in the axial direction. The flow profile in the channel is parabolic with the maximum velocity in the middle. External field (e.g., flow, thermal) applied in the perpendicular direction forces molecules to different distances from the channel wall, i.e., to different velocity layers. Thus, the elution time increases with decreasing distance of particles from the channel wall.

FFF can be used for separation of particles in the range of a few nanometers to tens of micrometers. In

**Figure 5** Extrapolation of light scattering intensities to zero angle for a single SEC elution volume slice; 16 angles in the range of  $17^\circ$ – $147^\circ$ . The intercept and initial slope provide molar mass and RMS radius, respectively.  $M = 1\,043\,000\text{ g mol}^{-1}$ ;  $R = 47.1\text{ nm}$ ;  $c = 3.38 \times 10^{-5}\text{ g ml}^{-1}$ .

combination with a MALS detector, the FFF technique becomes efficient for the determination of the molar mass and size distributions. An important advantage of FFF is that it is a very gentle method. Compared to SEC the method eliminates significantly the possibility of shearing degradation. The fact that the channel does not contain any packing eliminates the possibility of enthalpic interactions that may strongly affect SEC results. Nonexistence of packing also eliminates entanglement that can occur during SEC separation of large highly branched molecules.

### Matrix Assisted Laser Desorption Ionization Time-of-Flight Mass Spectrometry

In addition to MMD, MALDI-TOF mass spectrometry also provides compositional information (end groups and structure). However, in the case of polydisperse polymers MALDI commonly fails due to the mass dependent desorption ionization process or mass dependent detection efficiency. The inability of MALDI to provide reliable MMD for polydisperse polymers can be overcome by combination with SEC either by collecting SEC fractions and performing MALDI analysis offline or using a direct coupling. In the SEC-MALDI combination, the refractive index detector of the SEC instrument determines the polymer concentration and the corresponding molar mass is measured by MALDI. The determination of average molar masses of each fraction allows establishing the SEC calibration that can then be used to compute MMD by conventional SEC. However, the speed of the analysis and expensive instrumentation are the limitations of the SEC-MALDI methodology.

### Characterization of Long-Chain Branching

Long-chain branching (i.e., polymeric offshoots from a macromolecular chain) is another parameter strongly affecting polymer properties. Branching can arise from various side-reactions and is often overlooked in polymer characterization. The principle of the identification and characterization of long-chain branching is based on the fact that at a constant molar mass the molecular size decreases with increasing degree of branching. That means in order to characterize branching one has to obtain information about both the molar mass and the molecular size. Light scattering has been presented as the method providing simultaneously molar mass and RMS radius. However, the classical light scattering measurement of unfractionated sample provides molar mass and RMS radius of different moments ( $M_w$  versus  $R_z$ ) that cannot be directly compared.

**Table 2** Average branching ratio calculations for two randomly branched polystyrenes

Sample	Quantity	Experimental	Calculated for linear polymer	Equation used for calculation
#1	$[\eta]$ (ml g <sup>-1</sup> )	58.0	80.5	$[\eta] = 0.0117 \times M^{0.717}$
	$M_w$ (10 <sup>3</sup> g mol <sup>-1</sup> )	225	—	$R = 0.014 \times M^{0.585}$
	$R_z$ (nm)	26.8	37.4	
	$M_z$ (10 <sup>3</sup> g mol <sup>-1</sup> )	719	—	
	$g'$	—	0.72	
	$g$	—	0.51	
#2	$[\eta]$ (ml g <sup>-1</sup> )	82.5	146.5	$[\eta] = 0.0117 \times M^{0.717}$
	$M_w$ (10 <sup>3</sup> g mol <sup>-1</sup> )	519	—	$R = 0.014 \times M^{0.585}$
	$R_z$ (nm)	50.3	76.5	
	$M_z$ (10 <sup>3</sup> g mol <sup>-1</sup> )	2447	—	
	$g'$	—	0.56	
	$g$	—	0.43	

Branched samples can be characterized by the branching ratio (branching index) defined as the ratio of the mean square radii of the branched (br) and linear (lin) molecules at the same molar mass:

$$g = \left( \frac{R_{br}^2}{R_{lin}^2} \right)_M \quad [20]$$

An alternative branching ratio is based on the intrinsic viscosity:

$$g' = \left( \frac{[\eta]_{br}}{[\eta]_{lin}} \right)_M \quad [21]$$

The mutual relationship of the two branching ratios can be expressed as follows:

$$g^e = g' \quad [22]$$

where the draining parameter  $e$  varies in the range of 0.5–1.5.

The average  $g'$  for the unfractionated sample can be determined by measuring  $M_w$  with light scattering either in batch or SEC mode and the intrinsic viscosity with a viscometer. Then the intrinsic viscosity of the linear sample having the same  $M_w$  as the sample under investigation is calculated using the Mark–Houwink equation for the linear polymer. The branching ratio  $g'$  is calculated from the experimental and calculated intrinsic viscosities.

The average  $g$  can be calculated alike using the values of  $R_z$  and  $M_z$  determined by SEC–MALS. The RMS radius of a linear sample having the same  $M_z$  as the sample under investigation is calculated using the relation  $R = kM^b$  for the linear polymer. The average branching ratio  $g$  at the same  $M_z$  is calculated using the experimental and calculated RMS radii. Note: The two methods described do not provide identical results since the calculation is based on different size

parameters and different molar mass averages. Examples of calculation of average  $g$  and  $g'$  for two randomly branched polystyrene samples are given in **Table 2**.

The combined SEC–MALS technique overcomes the limitation of classical light scattering experiment since the molar masses and RMS radii are obtained for narrow fractions. Consequently, the branching ratio  $g$  can be determined as a function of molar mass. In addition, branching can be identified from the slope of the RMS radius versus molar mass plot even if the data for corresponding linear polymers are unavailable. However, the RMS radius versus molar mass plots may be biased by the abnormal elution behavior of some highly branched large molecules that can be entangled in the column packing and elute later together with smaller molecules and thus strongly increase the polydispersity within elution volume slices.

### Introduction

Polyurethanes are addition polymers containing the urethane linkage,  $\text{—RNHCOOR'—}$ . They have been of great commercial importance for 50 years, with many applications as foam (furniture and automotive seating, insulation, carpet underlay), coatings (automotive and architectural paint), adhesives and sealants, and as elastomers for a variety of special purposes.

Most synthetic polymers are made in chemical plants, with the completed products shipped to fabricators for final molding, spinning, blowing, etc. Polyurethanes are different in that the polymer itself is made on the spot in the facilities of appliance and furniture manufacturers, at automotive suppliers, and on construction sites. For example, polyurethane insulation is formed within the shell of a refrigerator during appliance assembly. Usually, there is no need to drive off reaction byproducts to force the reaction to completion and the polyurethane is formed without addition of heat.

### Analysis of Polyurethane Raw Materials

Since most industrial customers purchase raw materials and form the polyurethane at point of use, analysis of the raw materials is commercially more important and much more common than analysis of the polyurethane product. Raw materials are analyzed to confirm their identity and to assess their suitability for use. The formation of a polyurethane, like the formation of other polymers, is quite sensitive to the purity of the reagents. Since it is

impossible to purify the polymer once it is formed, any faults contributed by the raw materials remain part of the polymer for the life of the product.

In simplest terms, the raw materials for urethanes consist of compounds having two or more isocyanate groups and compounds having two or more hydroxyl groups. These hydroxy compounds, commonly called polyols, are most often polyethers and polyesters, although some other materials are also encountered.

### Polyols

Long, linear, difunctional polyols give flexibility to polyurethanes while short, branched, polyols with three or more hydroxyl groups per molecule impart rigidity. It is critical that the polyol has the molecular weight and functionality specified, and that it has the reactivity appropriate for the particular application. The reactivity is controlled by the presence of catalysts (whether they be impurities or deliberate additives) and by chemical functionality, most importantly whether the hydroxyl groups are primary or secondary, and whether the reactants contain amine groups.

The most important compounds are polyetherols, polyesterols, and graft polyols (**Figure 1**). Polyetherols are the most common polyols and most commercial products are made chiefly from ethylene oxide and propylene oxide. Polyesterols are widely used in elastomeric polyurethanes. Typical compounds are aliphatic polyesters, such as poly(ethylene adipate), made so that there are only hydroxyl end groups, with no residual acid groups. Graft polyols (also called polymer polyols) consist of a matrix of a conventional polyol, which also contains rubbery (such as styrene/acrylonitrile copolymer) particles chemically bound to polyol molecules. These 'grafted' particles reinforce the final polyurethane, giving improved physical properties.

### Introduction

Polyurethanes are addition polymers containing the urethane linkage,  $\text{—RNHCOOR'—}$ . They have been of great commercial importance for 50 years, with many applications as foam (furniture and automotive seating, insulation, carpet underlay), coatings (automotive and architectural paint), adhesives and sealants, and as elastomers for a variety of special purposes.

Most synthetic polymers are made in chemical plants, with the completed products shipped to fabricators for final molding, spinning, blowing, etc. Polyurethanes are different in that the polymer itself is made on the spot in the facilities of appliance and furniture manufacturers, at automotive suppliers, and on construction sites. For example, polyurethane insulation is formed within the shell of a refrigerator during appliance assembly. Usually, there is no need to drive off reaction byproducts to force the reaction to completion and the polyurethane is formed without addition of heat.

### Analysis of Polyurethane Raw Materials

Since most industrial customers purchase raw materials and form the polyurethane at point of use, analysis of the raw materials is commercially more important and much more common than analysis of the polyurethane product. Raw materials are analyzed to confirm their identity and to assess their suitability for use. The formation of a polyurethane, like the formation of other polymers, is quite sensitive to the purity of the reagents. Since it is

impossible to purify the polymer once it is formed, any faults contributed by the raw materials remain part of the polymer for the life of the product.

In simplest terms, the raw materials for urethanes consist of compounds having two or more isocyanate groups and compounds having two or more hydroxyl groups. These hydroxy compounds, commonly called polyols, are most often polyethers and polyesters, although some other materials are also encountered.

### Polyols

Long, linear, difunctional polyols give flexibility to polyurethanes while short, branched, polyols with three or more hydroxyl groups per molecule impart rigidity. It is critical that the polyol has the molecular weight and functionality specified, and that it has the reactivity appropriate for the particular application. The reactivity is controlled by the presence of catalysts (whether they be impurities or deliberate additives) and by chemical functionality, most importantly whether the hydroxyl groups are primary or secondary, and whether the reactants contain amine groups.

The most important compounds are polyetherols, polyesterols, and graft polyols (**Figure 1**). Polyetherols are the most common polyols and most commercial products are made chiefly from ethylene oxide and propylene oxide. Polyesterols are widely used in elastomeric polyurethanes. Typical compounds are aliphatic polyesters, such as poly(ethylene adipate), made so that there are only hydroxyl end groups, with no residual acid groups. Graft polyols (also called polymer polyols) consist of a matrix of a conventional polyol, which also contains rubbery (such as styrene/acrylonitrile copolymer) particles chemically bound to polyol molecules. These 'grafted' particles reinforce the final polyurethane, giving improved physical properties.

**Figure 1** Common types of polyols used in polyurethane products.

For two generations, wet chemical methods have been standard for quality control of polyols. Most of these methods are quite precise and give results directly related to suitability for use.

1. Hydroxyl number is a critically important parameter since it is the hydroxyl group which reacts with isocyanate to form the urethane linkage. The classical determination is by esterification of the hydroxyl groups with excess acetic anhydride or phthalic anhydride, followed by titration of the surplus reagent. Esterification remains the referee method, although it has been largely supplanted by near infrared (IR) spectrophotometry for routine quality control. Reaction with phenyl isocyanate is also sometimes used for hydroxyl determination, as is NMR spectrometry. Hydroxyl number by any of these techniques is indirectly proportional to number average molecular weight.
2. Acid number is of concern with both polyether and polyester polyols, since acidity affects the kinetics of the urethane reaction. Determination is by potentiometric titration.
3. Water content above a threshold value is critical because water reacts with isocyanate to form urea in a reaction competitive to urethane group formation. The determination is a straightforward application of the Karl Fischer titration, but precautions are necessary when weighing and transferring the sample because of the ease with which the polyol absorbs moisture from laboratory air. Usually, the sample is weighed out by difference from a disposable syringe.
4. Alkalinity is important because of its effect on reactivity. There is a potential for high alkalinity in polyether polyols, most of which are synthesized

using potassium hydroxide catalysis. Usually, the residual catalyst is removed by liquid–liquid extraction or by filtration. As an alternative or supplement to direct titration of alkalinity, residual sodium and potassium may be determined by atomic absorption or induction-coupled argon plasma emission spectroscopy. The latter approach is more convenient, since the polyol can be analyzed immediately after dilution in a suitably pure solvent, with no sample digestion required.

5. It is common in the industry to measure apparent pH of polyols after dissolution in an alcohol. Polyols with apparent pH below 4 or above 10 may give trouble in the urethane reaction. Because of poor reproducibility of measurements in the 5–9 range, there is less correlation with performance at intermediate apparent pH.

6. Nitrogen content (primary, secondary, tertiary) is important for reactivity considerations and is determined by classical nonaqueous potentiometric titration.

7. Reactivity is determined by mixing the polyol with an isocyanate compound, catalyst, and the other components of a standard foam recipe, then measuring the time required for maximum foam rise, maximum exotherm, or some related phenomenon.

8. Saponification number is characteristic of polyesters and is determined by titration.

9. Unsaturation is important for special cases, depending on the nature of the polyol. This is because, during polyetherol synthesis, an undesirable side reaction can lead to formation of a terminal double bond and no terminal hydroxyl group. The resulting polyol therefore has less functionality than intended.

10. Ash, color, refractive index, specific gravity, suspended matter, and viscosity are determined by traditional methods.

Most methods for quality control of polyols have been used internationally for decades and have official status as ASTM, or, in some cases, ISO standards. While there has been evolutionary change, most procedures have been altered little over the past generation.

Instrumental analysis is used more often for troubleshooting and research than for routine analysis.

1. Infrared and Raman spectroscopy are sufficient to identify the gross composition of polyols, but will not give the precise characterization of NMR spectroscopy. Near IR analysis is used in quality control laboratories for the determination of hydroxyl number and water, after calibration with a closely related set of polyols.

2. NMR spectrometry is used for determination of primary and secondary OH content and ethylene

oxide content, as well as determination of heteric (random) or block polyether structure and capping.

3. Gas chromatography (GC) is used mainly for determination of residual monomer and perhaps initiator fragments from the graft component.

4. Liquid chromatography (LC). While normal-phase or reversed-phase LC are sometimes applied for special purposes, the usual mechanism of polyol characterization is size-exclusion chromatography (SEC) using differential refractive index or evaporative light scattering detection. Many polyester polyols, for example, those based upon terephthalate esters, can also be detected by ultraviolet (UV) absorbance. SEC yields both number average and weight average molecular weight values, as well as information about the polydispersity and whether the polyol is a single polymer or is perhaps a blend of two or more components.

### Isocyanate Compounds

Toluene diisocyanate (TDI) and the various forms of methylene 4,4'-bis(phenylisocyanate) (MDI) are the most common isocyanate compounds in commercial polyurethanes. Aliphatic isocyanates (hexamethylene diisocyanate) are not generally used in foams, but

rather in elastomers, coatings, and other applications (Figure 2).

Because volatile isocyanate monomers present an industrial hygiene challenge, they are often supplied to the industrial user in a modified form. For example, an isocyanate-terminated 'prepolymer' may be formed by reacting an excess of isocyanate with the polyol to form a liquid material, which has little of the starting isocyanate. However, unless special measures are taken (e.g., reacting a large excess of diisocyanate monomer with the hydroxy compound, then stripping away the excess monomer), the prepolymer will contain free diisocyanate monomer and also oligomers of, for example, three molecules of diisocyanate reacted with two polyol molecules (Figures 3–5).

Because of the toxicity of isocyanates, laboratory operations are designed to minimize personal exposure and are performed in a fume hood. Exposure to high levels of isocyanates, particularly toluene diisocyanate, can cause 'sensitization' of a worker, so that afterward he/she cannot tolerate exposure even to levels of isocyanate considered safe for others.

Isocyanates react readily with the moisture in laboratory air, forming ureas, so stringent precautions are taken when sampling to avoid contamination by moisture. This is usually accomplished by purging the headspace of sample containers with a stream of dry gas, most conveniently nitrogen.

Wet chemical analysis of isocyanates is well established.

1. Isocyanate (NCO) content is critical for calculation of reaction stoichiometry. Total NCO content is

determined by reaction with excess dibutylamine to form a substituted urea, followed by titration of the unreacted dibutylamine with acid.

2. Hydrolyzable chlorine content is important because of the effect of acidity on reaction speed. Most isocyanates are made by phosgenation of the corresponding amines, and side reactions lead to the presence of what can be thought of as organic addition compounds of hydrochloric acid. These are hydrolyzed under more or less rigorous conditions to yield chloride ion, which is titrated in the usual way with silver nitrate solution. 'Total chlorine' content is related to overall purity of the isocyanate. It is determined by combustion of the organic matter in a Schöniger oxygen flask or Paar bomb, followed by measurement of liberated chloride ion by titration or by ion chromatography.

3. In the absence of additives, acidity is stoichiometrically equal to easily hydrolyzable chlorine, determined above, and is useful for predicting reactivity.

4. Properties such as viscosity, color, and specific gravity are determined by the usual industrial methods.

Instrumental analysis may include:

1. X-ray fluorescence is the most convenient technique to determine total chlorine and bromine content. Bromine may be introduced as an impurity in the phosgene used in isocyanate synthesis.
2. GC is suitable for the determination of many simple isocyanates, including the most common, namely TDI isomers and monomeric MDI isomers. Both assay and isomer content are determined, and GC is a useful method for determining the

residual monomeric diisocyanate content of prepolymers. Impurities such as solvents are also apparent by GC.

3. LC is used in production facilities to characterize MDI and its precursor, methylene dianiline (MDA). Either normal-phase or reversed-phase conditions can be used. The isocyanates must first be derivatized by reaction with an alcohol. The isomer composition is determined by LC, as well as the distribution of monomeric and 2- and 3-ring oligomeric components. LC complements SEC for MDI/MDA characterization.

4. SEC is an excellent method of characterizing higher molecular weight isocyanates such as polymeric MDI and prepolymers. The isocyanate end groups are derivatized with methanol to prevent reaction and the sample is subjected to conventional SEC using THF as solvent. Polymeric MDI oligomers are separated up to about the 5-ring compounds. In the case of prepolymers, clear separation is obtained of oligomers, together with a peak for the unreacted isocyanate compound. This latter is most easily quantified using an internal standard such as toluene. SEC is especially useful for studying the 'pot life' of prepolymers. Samples can be pulled from the prepolymer over the course of several hours, quenching the samples promptly in methanol. The whole series is then analyzed in batch mode at a convenient time to observe the changes in molecular weight distribution and free isocyanate as the batch ages. A warning: allophanate cross-linking of the prepolymer will not be seen by this technique, since the cross-linked material is insoluble in the SEC system.

5. Infrared spectroscopy is effective for detecting carbodiimide groups in isocyanates, as well as following dimer formation and other modification. In times past, IR was used for determining TDI isomer content, but now this is almost always performed by GC.

### Other Polyurethane Raw Materials

Besides the polyol and isocyanate, many other materials are used in polyurethanes, albeit in much lower volumes. These can be grouped into materials, which become part of the polyurethane matrix itself (such as chain extenders), and materials, which are additives physically but not chemically mixed with the polymer (such as antioxidants and blowing agents).

Chain extenders and cross-linkers (encountered especially in thermoplastic urethanes) are usually short diamines or diols, such as 1,4-butanediol or *tetrakis*(2-hydroxypropyl)ethylenediamine. Alkanolamines and triols like glycerol are also used. Most of these can be easily determined by GC.

Blowing agents are gases released during formation of the urethane which cause the final product to be a rigid or flexible foam. The main blowing agent in flexible foams is water, which forms  $\text{CO}_2$  by reaction with isocyanate groups. Carbon dioxide has disadvantages in rigid foam, especially in foam used for insulation. Chlorofluorocarbons, which boil at the temperature of the polyurethane reaction were used in the past, but are no longer found due to ecological considerations. Hydrochlorofluorocarbons and hydrofluorocarbons are still found, although they have been replaced for many purposes by simple hydrocarbons such as pentane.

Blocking agents are common in coatings. They prevent the cross-linking reaction from occurring until heat is applied. Phenols, alcohols, and other compounds, which react reversibly with isocyanates are used for this purpose. Most are readily determined by GC.

Oxidative stabilizers are added to prevent yellowing or 'scorching', especially in large foam blocks which develop high internal temperature during manufacture. Hindered phenols such as butylated hydroxytoluene are often used. Stabilizers are usually determined by HPLC or GC analysis, although UV absorbance measurement of a foam extract can often be used for quality control.

**Catalysts.** To make the final polyurethane, common catalysts are tertiary amines and organotin compounds, often used in mixtures. Amine catalysts favor the reaction of isocyanate with water, producing urea linkages and  $\text{CO}_2$ , which acts as a blowing agent. On the other hand, organotin catalysts favor the isocyanate/hydroxyl reaction. Additional catalysts and catalyst decomposition products may be present if graft polyols are part of the mixture. The most common of these catalysts are free radical initiators. Phosphorus compounds may be present in the case of carbodiimide-modified MDI.

Other materials may include pigments and fillers, surfactants, mold release/lubricants, and flame retardants. Coatings will have additional components, including UV stabilizers and hindered amine light stabilizers.

## Analysis of the Polymer

Most testing of polyurethane products is performed by specialists seeking information for well-defined purposes, whether it be to troubleshoot problems such as loss of physical properties, or perhaps to assess the ecological impact of the product in terms of what gases are released at equilibrium and under

**Figure 6** Linkages found in polyurethanes.

fire conditions, or what is the cause of a specific color or odor. Sometimes though, it is necessary simply to analyze the finished polyurethane in order to learn what are the chief components, namely, what were the isocyanate and polyol compounds from which it was made, and the catalysts, additives, blowing agents, and so on. This is a challenging task, because most polyurethanes cannot be dissolved without breaking chemical bonds and fundamentally changing the nature of the polymer.

Besides urethane bonds, other chemical functionalities are present due to reaction of isocyanate groups with water and other compounds. In fact, urea and isocyanurate bonds are more abundant than the urethane linkages in some commercial products that are designated as polyurethanes. Allophanate, biuret, urea, carbodiimide, and isocyanurate linkages may be found. These bonds certainly affect the properties of the final polymer, but unfortunately it is almost impossible to determine them quantitatively (Figure 6).

Polyurethane elastomers are made up of predominantly linear molecules which contain rigid and flexible segments. This is true whether the elastomer composes an elastic fiber for clothing (spandex) or a shock-absorbing component in an automobile. The rigid and flexible (also called hard and soft) segments are balanced to give the physical properties needed. The flexible segments are formed from longer diols, while the rigid segments are composed of short cross-linking units and the diisocyanate components.

## Direct Analysis of Polyurethanes

1. Infrared spectroscopy is effective for qualitative analysis of polyurethanes, confirming that the material is a polyurethane and, depending upon the

experience of the spectroscopist, even telling something about the raw materials. For example, IR can indicate whether a polyether or polyester polyol was used, whether the isocyanate component is aliphatic or aromatic, and if aromatic, whether a polymeric MDI was used. Because of overlapping absorbance bands, it is much more difficult to characterize a polymer in terms of urea, allophanate, carbodiimide, biuret, and urethane structures, and small differences between urethane polymers are undetectable by IR.

2. Solid-state NMR analysis is useful for special purposes, especially for understanding chemical changes caused by oxidation or other degradation reactions.

3. SEC is of limited applicability with polyurethanes. Some thermoplastic urethanes, including spandex, can be characterized by simply dissolving and performing conventional SEC analysis, although this is most valuable when used for comparative purposes rather than for developing absolute information. The more common cross-linked polyurethane foams used in furniture and insulation cannot be dissolved and analyzed, and in any case the concept of molecular weight is meaningless in such systems.

4. Quite a number of physical test methods are routinely applied to polyurethanes, both during development of the product and for quality control purposes. Their discussion is beyond the scope of this article, but it should be noted that most of the testing performed on the final product is physical property testing, with chemical analyses being comparatively rare.

5. Identification of cell gas. This analysis is almost always performed by GC-mass spectrometry (GC-MS), with the gas removed from the closed cells using a syringe or by crushing the foam in a closed container.

6. Filler content is usually determined by quantitatively ashing the polymer, then performing qualitative or quantitative analysis of the inorganic residue.

7. Flame retardants must be determined by methods specific for the individual compound. For melamine, this can be as simple as extracting a foam with hot water and measuring the material removed. Brominated flame retardants are most easily measured by X-ray fluorescence determination of total bromine.

8. Mold release and lubricants are usually extracted with a suitable solvent and identified qualitatively by IR or MS. Quantitative determination is rarely of interest, but is most easily performed by determination of the cation, if present. For example, zinc stearate is most easily determined by measuring the total zinc content.

## Analysis after Hydrolysis/Solvolysis

There is a substantial literature describing the decomposition of urethane compounds under various conditions of hydrolysis and solvolysis to give fragments chemically related to the materials that reacted to form the original polyurethane. Usually, the polyether polyols and chain extenders can be recovered as simple derivatives, while the isocyanate compounds are recovered as the amine analogs. The reaction products are recovered by liquid-liquid extraction at controlled pH, or perhaps by preparative liquid chromatography. In the more recent work, this degradation has been conducted online as part of pyrolysis GC-MS analysis. This can be a very rapid technique for qualitative analysis of a polymer, identifying the main components in only an hour or two.

Allophanate and biuret bonds in polyurethane foam can be determined by degrading the foam with amines and subsequently performing quantitative titrations. This methodology is not of interest for routine analysis but is sometimes useful for fundamental understanding of the polymerization reaction.

## Isocyanates and Amines in Prepolymers and Finished Products

Many useful methods have been published for the determination of trace isocyanates in air and in polyurethane products by derivatization and GC, LC, or SEC quantification. For example, industrial hygiene determination of TDI in air by OSHA method 42 is performed by drawing air through a filter impregnated with 1-(2-pyridyl)piperazine. Derivatives are formed during sampling, which are then determined by LC. Also of concern are the amine hydrolysis products of the isocyanates. For example, toluenediamine (TDA) may be monitored in furniture foam. This is generally accomplished by liquid-solid extraction or vacuum distillation, followed by GC or LC quantification.

## POTENTIOMETRIC STRIPPING ANALYSIS

**M Honeychurch**, University of Queensland, Brisbane, QLD, Australia

### Introduction

Potentiometric stripping analysis (PSA) has become more widely used over the last 20 years in part because of the advent of commercial instrumentation during that period. In many ways the method is analogous to voltammetric stripping methods insofar as it comprises an initial preconcentration step in which the analyte is accumulated onto or into the working electrode followed by a stripping step in which the analyte is 'stripped' back into solution. The electrochemical cell is under potentiostatic control during the accumulation period,  $t_{\text{acc}}$ ; however, during the stripping step the potentiostatic control is discontinued and the change in the working electrode potential versus time is measured. Therefore, the method is more appropriately termed chronopotentiometric stripping analysis. The output is a sigmoidal-shaped chronopotentiogram (**Figure 1**) with each plateau (parallel to the potential axis) corresponding to the transition or stripping time,  $\tau$ . This is analogous to a potentiometric titration with each plateau corresponding to an 'endpoint' equating to the complete reaction of the accumulated analyte with the difference being that the change in electrode potential is plotted versus time rather than versus the volume of titrant added.
